$$\left. \begin{aligned} \hat{R}(\phi, \theta, \chi) &= \exp(-i\phi \hat{I}_z) \exp(-i\theta \hat{I}_y) \exp(-i\chi \hat{I}_z) \\ \hat{R}^{-1}(\phi, \theta, \chi) &= \exp(i\phi \hat{I}_z) \exp(i\theta \hat{I}_y) \exp(i\chi \hat{I}_z) \end{aligned} \right\} \quad (68)$$

The Euler angles $\{\phi, \theta, \chi\}$ define rotations about the z , then y , then z again axes of the original coordinate system, which rotations carry the original coordinate system to coincide with the new one. The $D_{q'q}^{(k)}(\phi, \theta, \chi)$ are called the *Wigner rotation matrix elements*. The definition of these coefficients is rather involved, and will not be given here. They are defined and tabulated in numerous texts, such as the excellent one by Zare.¹⁰ Exponential operators like those in equation (68) as generators of rotations play a central role in the theoretical development of NMR. They, too, are discussed in great detail in Zare’s text.

It was noted in Section 2.1 that operators do not necessarily commute. A special shorthand notation is commonly used for *commutators* of operators, defined as follows:

$$\hat{A}\hat{B} - \hat{B}\hat{A} \equiv [\hat{A}, \hat{B}] \quad (69)$$

Using this notation, an equivalent, though perhaps less intuitive, definition of irreducible spherical tensor operators is provided by the following commutation relations:

$$\left. \begin{aligned} [\hat{I}_{\pm}, \hat{T}_{q,j}^{(k)}] &= \{(k \mp q)(k \pm q + 1)\}^{1/2} \hat{T}_{q \pm 1, j}^{(k)} \\ [\hat{I}_z, \hat{T}_{q,j}^{(k)}] &= q \hat{T}_{q,j}^{(k)} \end{aligned} \right\} \quad (70)$$

Note that one is free to choose either the positive or the negative square root in the coefficient in equation (70), and the result will still satisfy both commutation relations. Thus, we choose the one that satisfies equation (65). The following commutators are easily verified for spin- $\frac{1}{2}$ from equation (63):

$$[\hat{I}_z, \hat{I}_{\pm}] = \pm \hat{I}_{\pm}, \quad [\hat{I}_{\pm}, \hat{I}_{\mp}] = \pm 2\hat{I}_z \quad (71)$$

From equation (59), using equation (62), one can generate the following operators and verify that equation (71) holds for spin 1 also:

$$\left. \begin{aligned} \hat{I}_+ &\rightarrow \sqrt{2} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad \hat{I}_- \rightarrow \sqrt{2} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \\ \hat{I}_z &\rightarrow \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (72)$$

It can be shown⁶ that these commutation relations are true in general. These three matrices represent an irreducible spherical tensor operator of rank one just as was the case for spin- $\frac{1}{2}$ in equation (64), and the zeroth-order operator can be written as well. Note, however, that the required normalization factors are different:

$$\left. \begin{aligned} \hat{T}_0^{(0)} &= \frac{1}{\sqrt{3}} \hat{E} \rightarrow \frac{1}{\sqrt{3}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \\ \hat{T}_1^{(1)} &= -\frac{1}{2} \hat{I}_+ \rightarrow -\frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} \\ \hat{T}_{-1}^{(1)} &= \frac{1}{2} \hat{I}_- \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \\ \hat{T}_0^{(1)} &= \frac{1}{\sqrt{2}} \hat{I}_z \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \end{aligned} \right\} \quad (73)$$

It is easily verified that these operators are orthonormal and satisfy equation (70).

Using these four operators as a starting point, the problem of finding the other five basis operators for spin 1 can now be addressed. The required operators must be mutually orthogonal and orthogonal to the four already proposed. A logical extension of what has been done so far would be the five elements of an irreducible spherical tensor operator of rank two. For spin 1, the step-up operator can be applied twice to the eigenstate $|-1\rangle$ to produce first the $|0\rangle$ then the $|1\rangle$ eigenstate. The corresponding second-rank operator is $\hat{I}_+ \hat{I}_+$. The representation of this operator can be obtained in several ways according to what we have learned so far. Perhaps the easiest way is to square the matrix given in equation (72) and normalize the result to give

$$\hat{T}_2^{(2)} = \frac{1}{2} \hat{I}_+ \hat{I}_+ \rightarrow \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (74)$$

which is easily shown to satisfy equation (70). Equation (70) can now be used to successively generate the other members of the set as follows:

$$[\hat{I}_-, \hat{T}_2^{(2)}] = \{(2+2)(2-2+1)\}^{1/2} \hat{T}_1^{(2)} = -2\hat{T}_1^{(2)} \quad (75)$$

The negative square root is chosen so as to satisfy equation (65). Hence, we have

$$\begin{aligned}\hat{T}_1^{(2)} &= -\frac{1}{2}[\hat{I}_-, \frac{1}{2}\hat{I}_+\hat{I}_+] = -\frac{1}{4}[\hat{I}_-, \hat{I}_+\hat{I}_+] \\ &= -\frac{1}{4}(\hat{I}_-\hat{I}_+\hat{I}_+ - \hat{I}_+\hat{I}_+\hat{I}_-) \end{aligned} \quad (76)$$

Then substituting from equation (71) yields

$$\begin{aligned}\hat{T}_1^{(2)} &= -\frac{1}{4}\{\hat{I}_-\hat{I}_+\hat{I}_+ - \hat{I}_+(2\hat{I}_z + \hat{I}_-\hat{I}_+)\} \\ &= -\frac{1}{4}\{(\hat{I}_-\hat{I}_+ - \hat{I}_+\hat{I}_-)\hat{I}_+ - 2\hat{I}_+\hat{I}_z\} \\ &= -\frac{1}{4}\{(-[\hat{I}_+, \hat{I}_-]\hat{I}_+ - 2\hat{I}_+\hat{I}_z) \end{aligned} \quad (77)$$

Using equation (71) again gives the desired operator, and substitution from equation (72), gives the representation:

$$\hat{T}_1^{(2)} = \frac{1}{2}(\hat{I}_z\hat{I}_+ + \hat{I}_+\hat{I}_z) \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{bmatrix} \quad (78)$$

Applying the same procedure successively generates the other three operators. The $q = 0$ component is

$$\begin{aligned}\hat{T}_0^{(2)} &= -\sqrt{\frac{1}{6}}[\hat{I}_-, \hat{T}_1^{(2)}] \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}[\hat{I}_-, (\hat{I}_z\hat{I}_+ + \hat{I}_+\hat{I}_z)] \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}(\hat{I}_-\hat{I}_z\hat{I}_+ - \hat{I}_z\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+\hat{I}_z - \hat{I}_+\hat{I}_z\hat{I}_-) \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}\{(\hat{I}_- + \hat{I}_z\hat{I}_-)\hat{I}_+ - \hat{I}_z\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+\hat{I}_z \\ &\quad - \hat{I}_+(-\hat{I}_- + \hat{I}_-\hat{I}_z)\} \\ &= -\frac{1}{2}\sqrt{\frac{1}{6}}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+ + \hat{I}_z[\hat{I}_-, \hat{I}_+] + [\hat{I}_-, \hat{I}_+]\hat{I}_z) \\ &= \sqrt{\frac{1}{6}}\{2\hat{I}_z^2 - \frac{1}{2}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+)\} \rightarrow \frac{1}{\sqrt{6}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix} \end{aligned} \quad (79)$$

In this case, the negative phase is chosen arbitrarily, because equation (65) places no constraint on the phase of this operator. The $q = -1$ component is

$$\begin{aligned}\hat{T}_{-1}^{(2)} &= \sqrt{\frac{1}{6}}[\hat{I}_-, \hat{T}_0^{(2)}] \\ &= \frac{1}{6}[\hat{I}_-, \{2\hat{I}_z^2 - \frac{1}{2}(\hat{I}_+\hat{I}_- + \hat{I}_-\hat{I}_+)\}] \\ &= \frac{1}{6}(2\hat{I}_-\hat{I}_z^2 - 2\hat{I}_z^2\hat{I}_- + \frac{1}{2}\hat{I}_+\hat{I}_-\hat{I}_- - \frac{1}{2}\hat{I}_-\hat{I}_-\hat{I}_+) \\ &= \frac{1}{6}\{2(\hat{I}_- + \hat{I}_z\hat{I}_-)\hat{I}_z - 2\hat{I}_z(-\hat{I}_- + \hat{I}_-\hat{I}_z) \\ &\quad + \frac{1}{2}(2\hat{I}_z + \hat{I}_-\hat{I}_+)\hat{I}_- - \frac{1}{2}\hat{I}_-(-2\hat{I}_z + \hat{I}_+\hat{I}_-)\} \\ &= \frac{1}{2}(\hat{I}_z\hat{I}_- + \hat{I}_-\hat{I}_z) \rightarrow \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & -1 & 0 \end{bmatrix} \end{aligned} \quad (80)$$

Here the positive phase has been chosen to satisfy equation (65). The $q = -2$ component is

$$\begin{aligned}\hat{T}_{-2}^{(2)} &= \frac{1}{2}[\hat{I}_-, \hat{T}_{-1}^{(2)}] \\ &= \frac{1}{4}[\hat{I}_-, (\hat{I}_z\hat{I}_- + \hat{I}_-\hat{I}_z)] \\ &= \frac{1}{4}(-\hat{I}_z\hat{I}_-\hat{I}_- + \hat{I}_-\hat{I}_-\hat{I}_z) \\ &= \frac{1}{4}\{-(\hat{I}_- + \hat{I}_-\hat{I}_z)\hat{I}_- + \hat{I}_-(\hat{I}_- + \hat{I}_z\hat{I}_-)\} \\ &= \frac{1}{2}\hat{I}_-\hat{I}_- \rightarrow \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix} \end{aligned} \quad (81)$$

The positive phase has been chosen here, again arbitrarily. The same result could also be obtained by starting from $T_{-2}^{(2)}$ and stepping it up with I_+ . These nine operators given by equations (73), (74), and (78)–(81) form a complete basis set for spin 1. Of course, higher spin bases can be constructed in the same way; spin I will require irreducible spherical tensors of rank $k = 0, 1, 2, \dots, 2I$.

4 THE DENSITY OPERATOR

It is a familiar concept⁷ that an experimental measurement will yield a value corresponding to the bracket of the state of the system under study with the operator corresponding to the observable:

$$\langle \hat{O}(t) \rangle = \langle \psi(t) | \hat{O} | \psi(t) \rangle \quad (82)$$

The notation on the left-hand side carries some connotation that the operator is time-dependent, which need not be the case; the time dependence in this case is carried entirely in the state. Some authors use the notation $\langle \hat{O} \rangle(t)$ or some other variant to avoid possible ambiguity. We shall retain the notation of equation (82), trusting the reader to realize the subtle difference implied. This leads to a discussion of Schrödinger versus Heisenberg versus interaction pictures of quantum mechanics, which will be addressed in Section 4.1. Of course, this result is independent of the ‘picture’ employed or the basis chosen. Inserting twice the sum on projection operators for some basis as in equation (19) and rearranging yields

$$\begin{aligned}\langle \hat{O}(t) \rangle &= \langle \psi(t) | \sum_{i=1}^n |i\rangle \langle i| \hat{O} \sum_{j=1}^n |j\rangle \langle j| \psi(t) \rangle \\ &= \sum_{i,j=1}^n \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle \langle j | \psi(t) \rangle \\ &= \sum_{i,j=1}^n \langle j | \psi(t) \rangle \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle \end{aligned} \quad (83)$$

As in equation (9), the quantity $|\psi(t)\rangle \langle \psi(t)|$ can be regarded as an operator, which is known as the density operator $\hat{\rho}(t)$:

$$\hat{\rho}(t) = |\psi(t)\rangle \langle \psi(t)| \quad (84)$$

Continuing from equation (83), we can write

$$\begin{aligned}
 \langle \hat{O}(t) \rangle &= \sum_{i,j=1}^n \langle j | \hat{\rho}(t) | i \rangle \langle i | \hat{O} | j \rangle \\
 &= \sum_{j=1}^n \langle j | \hat{\rho}(t) \hat{O} | j \rangle \\
 &= \text{Tr}(\hat{\rho}(t) \hat{O})
 \end{aligned} \tag{85}$$

This is an important relationship showing that the expected value of any operator can be computed by taking the trace of its product with the density operator. This form is completely equivalent to equation (82), and is the form commonly used for discussion of magnetic resonance phenomena. Just as the state $|\psi(t)\rangle$ contains all that can be known about the state of a system, so does the density operator.

According to equation (42), using an appropriate operator basis, we can write

$$\begin{aligned}
 \hat{\rho}(t) &= \sum_{i=1}^{n^2} \text{Tr}[\hat{\rho}(t) \hat{U}_i^\dagger] \hat{U}_i \\
 &= \sum_{i=1}^{n^2} \langle \hat{U}_i^\dagger(t) \rangle \hat{U}_i
 \end{aligned} \tag{86}$$

Thus, the expected values of all the basis operators provide the coefficients needed to represent the density operator in any basis, and these values provide a Liouville space representation of the density operator according to equation (43). Extensive use of this concept will be made later in developing the equations needed to explain spin relaxation.

The development so far has implied that the system of interest can be characterized by a state $|\psi(t)\rangle$. Liquid samples can never be so characterized, but can often be viewed as an ensemble of such isolated systems. Thus, it is desirable to take an ensemble average of equation (84). Since all the variation among the members of the ensemble resides in the operator $|\psi(t)\rangle\langle\psi(t)|$, the averaging process commutes with the sums over basis states, and we can write

$$\begin{aligned}
 \overline{\langle \hat{O}(t) \rangle} &= \sum_{i,j=1}^n \overline{\langle j | \psi(t) \rangle \langle \psi(t) | i \rangle \langle i | \hat{O} | j \rangle} \\
 &= \sum_{i,j=1}^n \overline{\langle j | \hat{\rho}(t) | i \rangle \langle i | \hat{O} | j \rangle} \\
 &= \sum_{j=1}^n \langle j | \bar{\hat{\rho}}(t) \hat{O} | j \rangle \\
 &= \text{Tr}\{\bar{\hat{\rho}}(t) \hat{O}\}
 \end{aligned} \tag{87}$$

Clearly, $\hat{\rho}(t)$ can be replaced by $\bar{\hat{\rho}}(t)$ in the above equations, leaving the form of the equations the same. In what follows, we shall not retain the overbar notation, but the density operator should be assumed to be averaged over an ensemble.

4.1 Time Evolution of the Density Operator

The time-dependent Schrödinger equation

$$i\hbar \frac{d}{dt} |\psi(t)\rangle = \hat{\mathcal{H}}(t) |\psi(t)\rangle \tag{88}$$

can easily be converted to our density operator formalism. Beginning from equation (84) and using equation (88) and its complex conjugate obtained using equations (2) and (7), we can write

$$\begin{aligned}
 \frac{d\hat{\rho}(t)}{dt} &= \frac{d}{dt} \{ |\psi(t)\rangle \langle \psi(t)| \} \\
 &= \frac{d}{dt} \{ |\psi(t)\rangle \} \langle \psi(t)| + |\psi(t)\rangle \frac{d}{dt} \{ \langle \psi(t)| \} \\
 &= -\frac{i}{\hbar} \hat{\mathcal{H}}(t) |\psi(t)\rangle \langle \psi(t)| + \frac{i}{\hbar} |\psi(t)\rangle \langle \psi(t)| \hat{\mathcal{H}}(t) \\
 &= -\frac{i}{\hbar} \{ \hat{\mathcal{H}}(t) \hat{\rho}(t) - \hat{\rho}(t) \hat{\mathcal{H}}(t) \} \\
 &= -\frac{i}{\hbar} [\hat{\mathcal{H}}(t), \hat{\rho}(t)]
 \end{aligned} \tag{89}$$

Note that the Hamiltonian is Hermitian. The commutator of the Hamiltonian with the density operator determines the time development of the density operator. This relation is referred to as the *Liouville-von Neuman equation*, and will play a central role in what follows. Our goal, generally stated, will be to find solutions of this equation using a Hamiltonian corresponding to various experimental situations. The density operator at some particular time will generally be known—at least parametrically—and equation (89) must then be integrated to obtain the time development of the density operator.

The solution of this equation of motion is fairly simple if the Hamiltonian is not time-dependent. If we suppose that the density operator has the value $\hat{\rho}(0)$ at $t = 0$ then

$$\hat{\rho}(t) = \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \tag{90}$$

is a solution, as can be verified by differentiation:

$$\begin{aligned}
 \frac{d\hat{\rho}(t)}{dt} &= \left(-\frac{i}{\hbar} \hat{\mathcal{H}}\right) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \\
 &\quad + \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \left(\frac{i}{\hbar} \hat{\mathcal{H}}\right) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \\
 &= -\frac{i}{\hbar} \left\{ \hat{\mathcal{H}} \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \right. \\
 &\quad \left. - \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\mathcal{H}} \right\} \\
 &= -\frac{i}{\hbar} \{ \hat{\mathcal{H}} \hat{\rho}(t) - \hat{\rho}(t) \hat{\mathcal{H}} \} = -\frac{i}{\hbar} [\hat{\mathcal{H}}, \hat{\rho}(t)]
 \end{aligned} \tag{91}$$

We have used the fact that an operator commutes with a function of itself.

Now let us examine the expected value of a generic operator with this solution. Substituting equation (90) into equation (87) yields

$$\begin{aligned}
 \langle \hat{O}(t) \rangle &= \text{Tr}\{\hat{\rho}(t) \hat{O}\} = \text{Tr}\left\{ \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{O} \right\} \\
 &= \text{Tr}\left\{ \hat{\rho}(0) \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \hat{O} \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}} t\right) \right\} \\
 &= \text{Tr}\{\hat{\rho}(0) \hat{O}(t)\}
 \end{aligned} \tag{92}$$

The fact that the trace operation is invariant under cyclic permutation of the factors has been used, and the time-dependent operator $\hat{O}(t)$ has been introduced according to

$$\hat{O}(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}t\right) \hat{O} \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}t\right) \quad (93)$$

Equation (87) expresses the Schrödinger picture of quantum mechanics, whereas equation (92) transforms into the Heisenberg picture. Clearly, the two forms are equivalent.

Differentiating equation (93) yields the equation of motion for the time-dependent operators of the Heisenberg picture, corresponding to equation (89) for the Schrödinger picture:

$$\frac{d\hat{O}(t)}{dt} = \frac{i}{\hbar}[\hat{\mathcal{H}}, \hat{O}(t)] \quad (94)$$

The derivation proceeds like that of equation (91). The equations for the Schrödinger and the Heisenberg pictures are similar in form, but the sign differences in the various terms should be noted.

When the Hamiltonian is time-dependent, the situation is considerably more complex, and no attempt will be made here to discuss this case in general terms. However, suppose the Hamiltonian can be separated into a term that is time-dependent and another that is not:

$$\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_1(t) \quad (95)$$

Equation (89) may then be rewritten as

$$\begin{aligned} \frac{d\hat{\rho}(t)}{dt} &= -\frac{i}{\hbar}[\hat{\mathcal{H}}_0 + \hat{\mathcal{H}}_1(t), \hat{\rho}(t)] \\ &= -\frac{i}{\hbar}\{[\hat{\mathcal{H}}_0, \hat{\rho}(t)] + [\hat{\mathcal{H}}_1(t), \hat{\rho}(t)]\} \end{aligned} \quad (96)$$

If $\hat{\mathcal{H}}_1(t) = 0$ then the solution is as in equation (90). By analogy with equation (90), let us define the transformed operators

$$\hat{\rho}'(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \quad (97)$$

$$\hat{\mathcal{H}}_1'(t) = \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\mathcal{H}}_1(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \quad (98)$$

Differentiating equation (97) and substituting from equations (96) and (98) then gives

$$\begin{aligned} \frac{d\hat{\rho}'(t)}{dt} &= \frac{i}{\hbar}\hat{\mathcal{H}}_0 \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &\quad + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \frac{d\hat{\rho}(t)}{dt} \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &\quad + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \hat{\rho}(t) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0\right) \\ &= \frac{i}{\hbar}[\hat{\mathcal{H}}_0, \hat{\rho}'(t)] + \exp\left(\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \left(-\frac{i}{\hbar}\{[\hat{\mathcal{H}}_0, \hat{\rho}(t)]\right. \\ &\quad \left.+ [\hat{\mathcal{H}}_1(t), \hat{\rho}(t)]\}\right) \exp\left(-\frac{i}{\hbar}\hat{\mathcal{H}}_0 t\right) \\ &= -\frac{i}{\hbar}[\hat{\mathcal{H}}_1'(t), \hat{\rho}'(t)] \end{aligned} \quad (99)$$

Thus, in this ‘interaction picture’, part of the time dependence is placed in the operators and part remains in the density operator. The effect of $\hat{\mathcal{H}}_0$ appears only implicitly in the exponential transformation operator. Of course, this is not a solution of the equation of motion, but it will prove to be a useful technique to be applied later on.

4.2 The Reduced Density Operator

In NMR experiments, it is usually the case that the nuclear spins interact weakly with the other degrees of freedom of the sample of interest. For the moment, let us assume that they do not interact at all. The state of the system can be written as a direct product, as in equation (48a), of a ket corresponding to the spin degrees of freedom with one corresponding to the rest of the system, the lattice:

$$|S\rangle|L\rangle = |SL\rangle \quad (100)$$

The number of degrees of freedom, i.e., the number of basis states, necessary to span the spins is modest, while that necessary to span the lattice is very large—effectively infinite.

Consider the expected value of an operator that acts only on the spin degrees of freedom. If $\{|s\rangle\}$ is a basis set spanning both the spins and the lattice, we can write

$$\begin{aligned} \langle\hat{O}\rangle &= \text{Tr}(\hat{\rho}\hat{O}) = \text{Tr}(|SL\rangle\langle SL|\hat{O}) \\ &= \sum_{sl} \langle sl|SL\rangle\langle SL|\hat{O}|sl\rangle \end{aligned} \quad (101)$$

Since $\hat{O}$ commutes with the lattice operators, this can be rearranged to yield

$$\begin{aligned} \langle\hat{O}\rangle &= \sum_s \langle s|S\rangle\langle S|\hat{O}|s\rangle \sum_l \langle l|L\rangle\langle L|l\rangle \\ &= \sum_s \langle s|S\rangle \left(\sum_l \langle l|L\rangle\langle L|l\rangle \right) \langle S|\hat{O}|s\rangle \end{aligned} \quad (102)$$

We can now define the reduced density operator by

$$\hat{\sigma} = |S\rangle \left(\sum_l \langle l|L\rangle\langle L|l\rangle \right) \langle S| = \text{Tr}_l(\hat{\rho}) \quad (103)$$

The expected value of $\hat{O}$ can then be written as

$$\langle\hat{O}\rangle = \text{Tr}_s(\hat{\sigma}\hat{O}) \quad (104)$$

Thus, observing experimental quantities corresponding to spin operators requires only a knowledge of this reduced density operator, and the problem has, at least in principle, only the small dimensionality of the spin degrees of freedom and not the very large dimensionality of the spins and the lattice. In particular, the Liouville equation, equation (99), can be cast in this form. However, if there were, indeed, no interaction of the spins with the lattice, as was assumed above, there would be no relaxation. Of course, this is observed not to be the case, but the interaction is sufficiently weak that it can be treated by perturbation methods, and the very large number of

degrees of freedom in the lattice permits treating the lattice classically to achieve excellent correspondence of theory to experiment. In what follows, then, solutions will be sought of the Liouville–von Neuman equation for the reduced density operator:

$$\frac{d\hat{\sigma}(t)}{dt} = -\frac{i}{\hbar}[\hat{\mathcal{H}}(t), \hat{\sigma}(t)] \quad (105)$$

5 SUPEROPERATORS

The representation of operators in Liouville space has been discussed in Section 2.2. In this section, we shall introduce superoperators that act on operators in Liouville space in much the same way as operators act on states in Hilbert space, i.e., superoperators transform one operator into another.

Consider the operator product

$$\hat{C} = \hat{B}_1 \hat{A} \hat{B}_2 \quad (106)$$

Let us attempt to cast $\hat{A}$ in a Liouville space representation and then find a superoperator $\hat{B}$ such that $|\hat{C}\rangle = \hat{B}|\hat{A}\rangle$. The operator product can be written as follows and rearranged as shown by applying equations (7) and (15):

$$\begin{aligned} \langle i|\hat{C}|j\rangle &= \sum_{k,l=1}^n \langle i|\hat{B}_1|k\rangle \langle k|\hat{A}|l\rangle \langle l|\hat{B}_2|j\rangle \\ &= \sum_{k,l=1}^n \langle i|\hat{B}_1|k\rangle \langle j|\hat{B}_2^\dagger|l\rangle \langle k|\hat{A}|l\rangle \end{aligned} \quad (107)$$

The superoperator matrix elements can now be defined by

$$\langle ij|\hat{B}|kl\rangle = \langle i|\hat{B}_1|k\rangle \langle j|\hat{B}_2^\dagger|l\rangle \quad (108)$$

This expression can be viewed as the matrix elements of a direct product in a space with basis $|i\rangle|j\rangle = |ij\rangle$, the direct product of two identical Hilbert space bases as in equation (50):

$$\hat{B} = \hat{B}_1 \otimes \hat{B}_2^\dagger \quad (109)$$

The matrix elements of $\hat{A}$ may be mapped into a vector in this same space just as in equation (43). In fact, the operator basis $\{\hat{U}_i\}$ introduced in equation (43) is equivalent to the basis $\{|ij\rangle\}$. The matrix elements of $\hat{A}$ may be written as

$$\langle ij|\hat{A}\rangle = \langle i|\hat{A}|j\rangle \quad (110)$$

Then equation (107) can be written as

$$|\hat{C}\rangle = \hat{B}|\hat{A}\rangle \quad (111)$$

The utility of this formalism is evident from several examples.

5.1 Unitary Transformations

Unitary transformations like $\hat{U}\hat{A}\hat{U}^\dagger$ in Hilbert space can easily be translated to Liouville space using equation (109) to define the relevant superoperator

$$\hat{\hat{U}} = \hat{U} \otimes \hat{U} \quad (112)$$

Note that $(\hat{U}^\dagger)^\dagger = \hat{U}$. Then the unitary transformation becomes

$$\hat{\hat{U}}|\hat{A}\rangle \quad (113)$$

The superoperator $\hat{\hat{U}}$ is unitary. To show this, we can write

$$\hat{A} = \hat{U}^\dagger \hat{U} \hat{A} \hat{U}^\dagger \hat{U} \quad (114)$$

But this implies

$$|\hat{A}\rangle = (\hat{U}^\dagger \otimes \hat{U}^\dagger)(\hat{U} \otimes \hat{U})|\hat{A}\rangle = \hat{\hat{U}}^\dagger \hat{\hat{U}}|\hat{A}\rangle \quad (115)$$

where the second equality in equation (115) follows immediately by considering the adjoint of equation (108). Thus, it must be that

$$\hat{\hat{U}}^\dagger \hat{\hat{U}} = \hat{E} \quad (116)$$

5.2 Commutators

Consider the commutator $[\hat{A}, \hat{B}]$ as the action of something denoted by $[\hat{A},]$ on the operator $\hat{B}$ to produce a new operator $\hat{C}$. This relationship can be written as

$$[\hat{A}, \hat{B}] = \hat{A}\hat{B} - \hat{B}\hat{A} = \hat{A}\hat{B}\hat{E} - \hat{E}\hat{B}\hat{A} \quad (117)$$

Applying equation (109) then yields

$$\hat{\hat{A}} = \hat{A} \otimes \hat{E} - \hat{E} \otimes \hat{A}^\dagger \quad (118)$$

5.3 The Liouvillian

Using equation (118), the equation of motion for the density operator equation (89) can be re-written as

$$\frac{d|\hat{\rho}(t)\rangle}{dt} = -\frac{i}{\hbar}\hat{\hat{\mathcal{L}}}(t)|\hat{\rho}(t)\rangle \quad (119)$$

The Liouvillian superoperator corresponding to the commutator with the Hamiltonian is defined as

$$\hat{\hat{\mathcal{L}}}(t) = \hat{\mathcal{H}}(t) \otimes \hat{E} - \hat{E} \otimes \hat{\mathcal{H}}(t) \quad (120)$$

Note that the Hamiltonian is Hermitian, so that $\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}(t)^\dagger$.

1 INTRODUCTION

The manipulation of nuclear spin systems by rf fields and/or the observation of the signal they induce in a pick-up coil nearly always starts from an initial state characterized by one or several temperatures for the nuclear spins. The simplest example, that of a spin system of Hamiltonian $\mathcal{H}$ and single spin temperature T , corresponds to a density matrix for the spins of the form

$$\sigma = \exp(-\mathcal{H}/kT) / \text{Tr}[\exp(-\mathcal{H}/kT)] \quad (1)$$

The description of more complex cases can be found in textbooks.¹⁻³

In the vast majority of the uses of NMR, the characteristic frequencies ω associated with the Hamiltonian (for instance, in the Zeeman case, the Larmor frequency) are such that we have

$$\hbar\omega \ll kT \quad (2)$$

In such a case it is permissible, for most practical purposes, to replace the exact density matrix [equation (1)] by the expansion

$$\sigma \simeq (1 - \beta\mathcal{H}) / \text{Tr}(1) \quad (3)$$

where $\beta = 1/kT$ is called the ‘inverse temperature’. This is known as the ‘high-temperature approximation’, and it brings about an enormous simplification in the theoretical handling of NMR—most quantities of interest are linear in the inverse temperature β (with the exception of entropy, which is quadratic in β), so that their relative values are independent of spin temperature.

Low spin temperature NMR deals with the case when equation (2) is not valid and one has to use the full expression [equation (1)] for the density matrix. This leads to so-called ‘nonlinear effects’ in spin temperature, and eventually to nuclear magnetic ordering. There is an exception to the above statement; this is the case when equation (2) is valid as regards the nuclear frequencies, but when the nuclear spins are used

to probe the properties of systems at low temperature, which depend strongly on temperature. Examples are electronic ferro-, antiferro-, or ferri-magnets, or superfluid helium-3. These cases are explicitly omitted from the present article.

Low nuclear spin temperatures do not occur spontaneously in nature. Indeed, their production turns out to be extremely laborious, and it can only be justified by the pursuit of a valuable end. This means that, by contrast with the quasigeneral usage in the high-temperature domain, in low spin temperature NMR the nuclear spins are not used as probes of other systems [e.g. proteins or high T_c superconductors (see *High Temperature Superconductors*)], but they are the system whose properties are studied for their own sake: actors rather than spectators. The ‘valuable’ aim is essentially nuclear magnetic ordering.

After a brief description of the methods of production of low nuclear spin temperatures, we analyze some of the properties of such systems. In general, the discussion is limited to the domain of paramagnetism. Nuclear ordering, which is described elsewhere in this Encyclopedia (see *Nuclear Ferromagnetism and Antiferromagnetism* and *Thermodynamics of Nuclear Magnetic Ordering*), will only occasionally be touched upon.

This article is to a large extent inspired by Chapter 5 in the book by Abragam and Goldman,⁴ although here greater emphasis is put on the ideas behind and the principles of the formal calculations rather than on their detailed description.

2 METHODS OF PRODUCTION OF LOW NUCLEAR TEMPERATURES

The most obvious method is known under the delicate name of the ‘brute force’ method. It consists of waiting for thermal equilibrium with the lattice at a very low temperature of nuclear spins in a very high magnetic field. Let us give figures. Since both $\hbar\omega = h\nu$ and kT are energies, it is possible to express temperature in terms of frequency, and vice versa. It is useful to remember that 1 K $\simeq$ 20.8 GHz, or

$$1 \text{ mK} \simeq 20.8 \text{ MHz} \quad (4)$$

so that a ‘low’ Zeeman temperature would correspond to several millikelvin in a field of several tesla. The only problem involves the time required for the nuclear Zeeman interaction to reach equilibrium with the lattice, i.e. the length of the longitudinal relaxation time T_1 . In insulators, where nuclear relaxation is due to paramagnetic centers, T_1 becomes extremely long at low lattice temperature and in high field may reach a few hundred hours. Even though much shorter than predicted theoretically, for reasons not yet understood, such values of T_1 deprive the ‘brute force’ method of its attraction. The situation is different with metals, because their relaxation by the Korringa mechanism is much faster, and the ‘brute force’ method has been used with success for various metals. It should be noted that at high field, when the Zeeman interaction dominates all other interactions, a low spin temperature corresponds to a high nuclear polarization, through the relationship

$$P = B_I(\hbar\omega/kT) \quad (5)$$

where B_I is the Brillouin function for a nucleus of spin I . For the simplest case, i.e. spin $\frac{1}{2}$, this function is

$$B_I(x) = \tanh(x/2) \quad (6)$$

It is apparent from equation (5) that the polarization depends only on the ratio ω/T , i.e. the same physical state would be obtained with a different temperature, by varying the Larmor frequency in proportion. Therefore, the concept of temperature itself is of limited interest and for NMR in high field, ‘high-polarization NMR’ would be a more appropriate description than ‘low spin temperature NMR’. The necessity for a low lattice temperature is a mere consequence of the practical limitations on the value of the external field.

For insulators, a successful alternative to the inefficient ‘brute force’ method is dynamic nuclear polarization (DNP) which results from the EPR off-resonance irradiation of paramagnetic centers introduced purposely at low concentration in the solid. The basic phenomenon is the following: if electronic spins of Larmor frequency ω_e are irradiated at a frequency $\omega \neq \omega_e$, each time a photon is absorbed the energy of the system increases by $\hbar\omega$, and an upwards electronic spin-flip is produced, resulting in an increase in the electronic Zeeman energy of $\hbar\omega_e$. The energy imbalance $\hbar(\omega_e - \omega)$ serves eventually to modify the Zeeman energy of the nuclear spins.

In its first version, corresponding to the so-called ‘solid effect’,⁵ the irradiation frequency is the difference between or the sum of the electronic and nuclear Larmor frequencies $\omega_e \pm \omega_n$. The transitions are ‘forbidden’ flip-flop transitions or flip-flip transitions of an electron and a nuclear spin, which can only take place due to the dipolar interaction between these spins. Flip-flop transitions at $\omega_e - \omega_n$ yield a nuclear polarization parallel to the equilibrium value, and flip-flip transitions at $\omega_e + \omega_n$ yield a nuclear polarization of opposite sign. Under strong irradiation and in the absence of parasitic nuclear relaxation, the nuclear polarization modulus eventually becomes equal to that of the thermal equilibrium electronic polarization.

In many cases, when the EPR linewidth exceeds the nuclear Larmor frequency ω_n , the mechanism of DNP is different: off-resonance microwave irradiation produces allowed electronic transitions which lead to a cooling of the electron spin–spin reservoir. As this reservoir is in thermal contact with the nuclear Zeeman reservoir, the latter also becomes cooled, resulting in an increase in its polarization modulus. The sign is the same as for the solid effect: for $\omega < \omega_e$ it corresponds to a positive spin temperature and for $\omega > \omega_e$ to a negative spin temperature. Detailed descriptions of DNP are given by Abragam and Goldman.^{4,6}

Physicists are interested not only in nuclear spins with low Zeeman temperatures, but also in spins whose low temperature affects their spin–spin interactions: dipolar, indirect (in heavy nuclei), or RKKY^{1,3} (in metals). One can start from nuclei with large polarizations (low Zeeman temperatures) and perform an adiabatic demagnetization. This has been done for ‘brute force’ polarized nuclei^{7,8} and DNP-polarized nuclei in insulators (see e.g. Abragam and Goldman,⁴ Chapters 5 and 8). The adiabatic demagnetization can be done by actually reducing the field to zero, in which case the final interactions are the full spin–spin interactions. It can also be done at high field, by slowly sweeping an rf field from a frequency far off-resonance down to on-resonance. As a result of this

adiabatic demagnetization in the rotating frame (ADRF),⁹ it is the effective field in the rotating frame that is reduced to zero, and the remaining interactions are the so-called ‘secular spin–spin interactions’, consisting of that part of the spin–spin interactions which commutes with the Zeeman coupling.^{1,2}

In zero field, either actual or effective, the nuclear polarization vanishes, and ‘high-polarization NMR’ is no longer an adequate description. One quantity that is conserved in adiabatic demagnetization is the entropy of the system. The large initial nuclear polarization corresponds to a low entropy, and the only adequate title for this article should therefore be ‘low-entropy NMR’.

3 THE RESONANCE SIGNAL

It is well known from general principles (i.e. linear response theory¹⁰) that the CW nuclear absorption signal is the Fourier transform of the FID signal observed after an infinitely small pulse θ (see e.g. Goldman,¹¹ Chapter 1). It is then sufficient to analyze the signal observed after such a pulse.

We consider, for simplicity, a system with Zeeman and dipolar interactions having a density matrix of the form

$$\sigma_0 = \exp\left(-\sum_{\mu} \beta_{\mu} Z_{\mu} - \beta_D \mathcal{H}'_D\right) / \text{Tr}\{\exp(\dots)\} \quad (7)$$

where Z_{μ} is the Zeeman interaction $\omega_{\mu} I_z^{\mu}$ of the nuclear species μ , β_{μ} is the corresponding inverse spin temperature, $\mathcal{H}'_D$ is the secular dipolar interaction, and β_D its inverse temperature. This is transformed by a pulse θ at the Larmor frequency of species 0 into

$$\sigma(0) = \exp(-i\theta I_x^0) \sigma_0 \exp(i\theta I_x^0) \quad (8)$$

Its subsequent evolution is

$$\sigma(t) = \exp(-i\mathcal{H}t) \sigma(0) \exp(i\mathcal{H}t) \quad (9)$$

where $\mathcal{H}$ is the (supposedly static) Hamiltonian. In an appropriate rotating frame, $\mathcal{H}$ reduces to $\mathcal{H}'_D$. The expectation value of a quantity Q is

$$\langle Q \rangle(t) = \text{Tr}\{Q\sigma(t)\} \quad (10)$$

When the angle θ is infinitely small, equation (8) yields, to first order (linear response)

$$\sigma(0) \simeq \sigma_0 - i\theta [I_x, \sigma_0] \quad (11)$$

and the FID signal $\langle I_+ \rangle(t)$ (a transverse vector expressed in the form of a complex number) becomes

$$\langle I_+ \rangle(t) = -i\theta \text{Tr}\{I_+ \exp(-i\mathcal{H}'_D t) [I_x, \sigma_0] \exp(i\mathcal{H}'_D t)\} \quad (12)$$

or, after a few manipulations,

$$\langle I_+ \rangle(t) = -i\theta \langle [I_+(t), I_x] \rangle_0 \quad (13)$$

with the notation

$$Q(t) = \exp(+i\mathcal{H}'_D t) Q \exp(-i\mathcal{H}'_D t) \quad (14)$$

$$\langle Q \rangle_0 = \text{Tr}\{Q\sigma_0\} \quad (15)$$

3.1 Difference of the High-Temperature Case

We consider, for simplicity, a density matrix corresponding to pure Zeeman order for a system of identical spins $\frac{1}{2}$, I_i :

$$\begin{aligned}\sigma_0 &= \exp\left(-\beta \sum I_z^i\right) / \text{Tr}\left\{\exp\left(-\beta \sum I_z^i\right)\right\} \\ &= \prod_i (1 - t_\beta I_z^i)\end{aligned}\quad (16)$$

where

$$t_\beta = \tanh\left(\frac{1}{2}\beta\omega_0\right) \quad (17)$$

This is transformed by the θ pulse [equation (8)] into

$$\sigma(0) = \prod_i [1 - t_\beta (\cos\theta I_z^i + \sin\theta I_y^i)] \quad (18)$$

The FID of spin I_i , which is representative of the total FID, is then

$$\langle I_+^i \rangle = -t_\beta \sin\theta \text{Tr} \left\{ I_+^i(t) I_y^i \prod_{j \neq i} [1 - t_\beta (\cos\theta I_z^j + \sin\theta I_y^j)] \right\} \quad (19)$$

In the low θ limit, pertaining to the analysis of the absorption signal, this yields

$$\langle I_+^i \rangle = -t_\beta \theta \text{Tr} \left\{ I_+^i(t) I_y^i \prod_{j \neq i} (1 - t_\beta I_z^j) \right\} \quad (20)$$

It is easily shown that this is identical to equation (13). At high temperature, $t_\beta \simeq \frac{1}{2}\beta\omega_0 \ll 1$, so that $\prod_j (\dots) \simeq 1$, and one obtains

$$\langle I_+^i \rangle = -\frac{1}{2}\beta\omega_0\theta \text{Tr}\{I_+^i(t) I_y^i\} \quad (21)$$

It is the fact that t is no longer negligible at low temperature which distinguishes the low-temperature case from the high-temperature one. We end this subsection by emphasizing two of the conspicuous consequences of this difference:

1. It is apparent from equation (19) that, even with one nuclear species and purely Zeeman initial order, the FID shape does depend on the pulse angle θ . This observation has had two main consequences.
 - (i) A great surprise, after its experimental discovery, for a Ph.D. student of J. S. Waugh (private communication).
 - (ii) A disproof, or rather a correction, of the so-called ‘Lowe–Norberg theorem’¹² that the CW signal is the Fourier transform of the FID signal. This theorem stems from the fact that under the two conditions of high temperature and purely Zeeman order the FID signal following a rf pulse is proportional to $\sin\theta$, but its shape is independent of θ , as can be seen from equation (21). This fact, which was known earlier [E. M. Purcell, NMR Lectures Notes, Harvard (1953); A. Abragam, NMR Lectures Notes, Saclay (1955)], is really an extension of the validity of a general theorem that the CW signal is the

Fourier transform of the FID signal following a pulse of infinitely small angle θ , a consequence of linear response theory¹⁰ (see also Abragam and Goldman,⁶ Chapter 1, and Goldman,¹¹ Chapter 1).

2. In the case when there are several different polarized nuclear species, and/or secular dipolar order (nonnegligible β_D) in addition to Zeeman order, the FID signal shape of *one* nuclear species depends on *all* spin temperatures. It should be noted that, in the case of Zeeman plus dipolar order, the FID signal of spins I_μ depends on both β_μ and β_D , and on the angle θ , even at high temperature.²

3.2 Qualitative Features of the Zeeman Signal

We refer again to the FID signal following a pulse of infinitely small angle θ , but starting from a state of pure Zeeman order [$\beta_D = 0$ in equation (7)]. By contrast with the high-temperature case, the absorption signal shape is, in general, not symmetrical, and not centered on the Larmor frequency. This manifests itself by the fact that this CW signal has no vanishing odd moments. This can be shown by simple qualitative arguments that are not given here. Furthermore, all moments, whether odd or even, depend on the polarization, i.e. the shapes of the FID signal or absorption signal depend on the polarization. There is, however, a property of the high-temperature case that remains true for low temperature: the area of the absorption signal of a given nuclear species is proportional to its polarization. (This is also the initial FID signal following a small θ pulse). This property, which is associated with the polarization dependence of the first few moments of the absorption signal (i.e. the first few derivatives of the FID at $t = 0$), makes it possible to perform an absolute calibration of the nuclear polarizations. This has still another advantage, resulting from the following properties:

1. By manipulation of equation (13) one can derive a simple relationship between the integral of the absorption signal $-\int_{-\infty}^{+\infty} \langle I_y \rangle (\omega - \omega_0) d\omega$ and the nuclear polarization. The absorption signal thus defined corresponds to a nonsaturating rf field ω_1/γ along Ox in the rotating frame.
2. The ‘absorption’ voltage detected is

$$V(\omega) = \xi \omega_1 \langle I_y \rangle (\omega) \quad (22)$$

where ξ is a factor depending on the coil and on the receiver amplification.

Once one has a calibration of the nuclear polarization, the experimental integral

$$\int V(\omega) d\omega \quad (23)$$

yields a calibration of the product $\xi \omega_1$. Since, as will be seen later, ω_1 can be independently calibrated, we obtain the value of the so-called spectrometer ‘gain factor’ ξ , which can be used to calibrate other physical quantities of interest. This is essential in a domain where everything is highly nonlinear.

Of course, it is equivalent to use the formal expression of the initial FID $\langle I_y \rangle$ following a small-angle pulse and the initial experimentally detected voltage.

3.3 The Moments of the Zeeman Absorption Signal

This section deals only with results, and qualitative comments are made. Detailed calculations can be found in, for example, Abragam et al.¹³ and Roinel and Bouffard.¹⁴

3.3.1 The First Moment

The first moment of the absorption signal (with respect to the Larmor frequency) characterizes the overall shift in the resonance frequency, irrespective of any change in signal shape. The Larmor frequency is determined as the low-polarization limit of the frequency with respect to which the first moment vanishes. One must distinguish between cases when there are one or several spin species.

3.3.1.1 One spin species: the $\frac{3}{2}$ effect. By this we mean nuclear spins with the same chemical shift and the same nuclear environment, e.g. ^{19}F in CaF_2 . Conversely, KMgF_3 contains three imbricated simple cubic arrays of ^{19}F nuclei which, for a given field orientation, differ both in their secular dipolar couplings and in their chemical shifts.¹⁵

For a simple spin species, the first moment is not equal to the average (Weiss) field experienced by the spins of other nuclei, rather it is $\frac{3}{2}$ times larger. This can be illustrated as follows. The secular dipolar interaction experienced by a spin I_i is

$$\mathcal{H}_D^{(i)} = \frac{\gamma^2 \hbar}{2} \sum_j \frac{1 - 3 \cos^2 \theta_{ij}}{r_{ij}^3} \{2I_z^i I_z^j - I_x^i I_x^j - I_y^i I_y^j\} \quad (24)$$

The term inside the braces can be written

$$\{\dots\} = \{2I_z^i \langle I_z^j \rangle + 2I_z^i (I_z^j - \langle I_z^j \rangle) - I_x^i I_x^j - I_y^i I_y^j\} \quad (25)$$

It might seem that the first term on the right-hand side will contribute to the shift of the signal, whereas the remaining terms, corresponding to short-range correlations, affect only the lineshape. This argument is wrong. Indeed, we may write the term in braces in equation (24) in the form

$$\{\dots\} = \{3I_z^i I_z^j - \mathbf{I}^i \cdot \mathbf{I}^j\} \quad (26)$$

The scalar product commutes with

$$I_+ = I_+^i + I_+^j + \sum_{k \neq i, j} I_+^k \quad (27)$$

and it does not contribute to the FID derivative at $t = 0$ (proportional to $\langle [I_+, \mathcal{H}_D] \rangle$). The remaining term is

$$3I_z^i I_z^j = 3I_z^i \langle I_z^j \rangle + 3I_z^i (I_z^j - \langle I_z^j \rangle) \quad (28)$$

The first term on the right-hand side contributes to the first moment, and the second one to the lineshape; thus the ' $\frac{3}{2}$ effect' is recovered. What was wrong with the first reasoning? This was pinpointed by Kittel.¹⁶ We have tacitly assumed in equation (25) that only the longitudinal spin components have nonvanishing average values. In the presence of rf irradiation,

the transverse components no longer vanish, and one should use

$$I_x^i I_x^j = I_x^i \langle I_x^j \rangle + I_x^i (I_x^j - \langle I_x^j \rangle) \quad (29)$$

and similarly for the I_y terms. The Weiss fields originating from these transverse components, however small, are sufficient to account for the $\frac{3}{2}$ effect.

Owing to the long range of the dipolar couplings [equation (24)], the NMR first moment depends on the sample shape. The only case for which the Weiss field is the same for all spins is when the sample is ellipsoid in shape. Otherwise, there is a distribution of Weiss fields, and hence an extra broadening of the line. The case when the first moment vanishes is that of a spherical sample of nuclear spins in cubic symmetry, such as ^{19}F in CaF_2 . It is only when the first moment does not vanish that it can be used for polarization calibration.

3.3.1.2 Several spin species. We consider the case where there are only two species from different nuclear elements, e.g. LiF or LiH. We call the spins I and S . There is no ' $\frac{3}{2}$ effect' between unlike spins, because they precess at different frequencies. The first moments of the two NMR signals are of the form

$$m_{1I} = \frac{3}{2} B_{I \rightarrow I} I p_I + B_{S \rightarrow I} S p_S \quad (30a)$$

$$m_{1S} = B_{I \rightarrow S} I p_I + \frac{3}{2} B_{S \rightarrow S} S p_S \quad (30b)$$

where p_I and p_S are the polarizations.

The various Weiss fields (or their average values in nonellipsoidal samples) can be calculated theoretically. The variation in the moments with the absorption signal areas then yields an absolute calibration of the polarizations. Figure 1 illustrates the use of this method for LiF. The method is easily extended to more than two species.

3.3.2 The Second Moment

Consider the case when the first moment vanishes, for instance that of ^{19}F in a sphere of CaF_2 . The theoretical expression of the second moment is¹³

$$M_2 = \langle [\mathcal{H}_D', I_+] [I_-, \mathcal{H}_D'] \rangle_0 / \langle I_+ I_- \rangle_0 \quad (31)$$

For spins $\frac{1}{2}$, equation (31) yields the following dependence on the nuclear polarization p :

$$M_2(p) = M_2(0)(1 - p^2) \quad (32)$$

One should then observe a linear variation of the experimental M_2 as a function of the square of the signal area.

Figure 2 shows that this is actually the case, for two spherical samples of CaF_2 . The only problem is that the value of M_2 extrapolated to zero polarization is larger than its theoretical value, and different in the two samples. The origin is in the presence of paramagnetic centers at low concentration (Tm^{2+} in the present case), which produce a Lorentzian distribution of fields at the ^{19}F sites.¹³ The two samples have different Tm^{2+} concentrations, and thus different

Figure 1 Experimental first moments (to within an arbitrary constant) of ${}^7\text{Li}$ and ${}^{19}\text{F}$ against their best-fit value in a parallelepiped of LiF . (Reproduced by permission of Oxford University Press from Abragam and Goldman⁴)

Figure 2 Second moment of the ${}^{19}\text{F}$ absorption signal against its area squared (in arbitrary units), for two spherical samples of CaF_2 , with $\mathbf{B}_0 \parallel [100]$. (Reproduced with permission from Abragam et al.¹³)

values of the second-moment excess. This excess depends slightly on nuclear polarization, as derived in Abragam et al.¹³

3.3.3 Higher Moments

These moments also depend on polarization, and could potentially be used for polarization calibration. In particular, for a simple cubic system of spins $\frac{1}{2}$ in a sphere, one predicts for the third moment

$$M_3 \propto p(1 - p^2) \quad (33)$$

which goes through a maximum for $p = 1/\sqrt{3}$. Experimentally, it is extremely difficult to avoid ‘contamination’ of the absorption signal by a small dispersion contribution, whose antisymmetric shape in the wings is sufficient to deprive experimental third moments of any significance.

4 RIGOROUS NMR RESULTS

We list below several results derived theoretically from equation (13). These results are rigorous for systems in the paramagnetic state, that is with an initial density matrix of the form given by equation (1) in an appropriate reference frame. From plausibility arguments, one is inclined to think that many remain valid even in nuclear magnetic ordered states, that is under conditions of symmetry breaking when equation (1) cannot be rigorous.

Each of these results has been implemented experimentally and used as a practical tool for the investigation of spin systems at low temperature. We cite and comment on these investigations, but no detailed calculations are given. We have already described the first investigation, which is concerned with the area of the absorption signal which, after calibration, yields both the polarization and the ‘gain coefficient–rf field’ product $\xi\omega_1$.

4.1 Rate of Change of the Polarization

Consider for simplicity a single-species system subjected to a small rf irradiation at a distance Δ from resonance. Its Hamiltonian in the rotating frame is

$$\mathcal{H} = \Delta I_z + \omega_1 I_x + \mathcal{H}'_D \quad (34)$$

According to the Liouville–von Neumann evolution equation for the density matrix, the rate of change in the longitudinal spin expectation is

$$\begin{aligned} \frac{d}{dt} \langle I_z \rangle &= \text{Tr} \left\{ I_z \frac{d\sigma}{dt} \right\} \\ &= \text{Tr} \{ -i I_z [\mathcal{H}, \sigma] \} \\ &= \text{Tr} \{ -i [I_z, \mathcal{H}] \sigma \} \\ &= \langle -i [I_z, \mathcal{H}] \rangle_0 \end{aligned} \quad (35)$$

and thus, according to equation (34)

$$\frac{d}{dt} \langle I_z \rangle = \omega_1 \langle I_y \rangle \quad (36)$$

If one monitors the absorption signal during an irradiation process, the total change is given by

$$\delta \langle I_z \rangle = \int \omega_1 \langle I_y \rangle dt \quad (37)$$

Use has been made of this method to measure the longitudinal susceptibility in demagnetized spin systems.¹⁷

The basis of the method is as follows. Starting from equilibrium after ADRF, i.e. an initial density matrix

$$\sigma_i = \exp(-\beta_i \hat{\mathcal{H}}'_D) / \text{Tr}\{\dots\} \quad (38)$$

a saturating rf field is suddenly applied at a (small) distance Δ from resonance and one monitors the absorption signal over the course of the evolution of the system towards a new equilibrium of density matrix

$$\sigma_f = \exp[-\beta_f (\mathcal{H}'_D + \Delta I_z + \omega_1 I_x)] / \text{Tr}\{\dots\} \quad (39)$$

If Δ and ω_1 are much smaller than the local field, one has $\beta_f \simeq \beta_i$, and

$$\delta \langle I_z \rangle = \langle I_z \rangle_f = \omega_1 \chi_{\parallel}(\beta) \quad (40)$$

This is measured from the absorption signal using equation (37) and the calibrated value of $\xi \omega_1$.

4.2 Slightly Saturating Linear Passages

We consider a linear sweep of the field (or irradiation frequency) through resonance, with the time of sweep of the linewidth being much longer than T_2 . The irradiation produces a saturation of both the polarization and the dipolar energy, which we presume to be small.

4.2.1 Saturation of the Polarization

Let $d\Delta/dt = \dot{\Delta}$. Equation (37) then yields

$$\delta \langle I_z \rangle = \frac{\omega_1}{\dot{\Delta}} \int_{-\infty}^{+\infty} \langle I_y \rangle(\Delta) d\Delta \quad (41)$$

The limits can be taken equal to $-\infty$ and $+\infty$ if the sweep starts well below resonance and ends well above it. The integral of the absorption signal is precisely related to the value of $\langle I_z \rangle$, which yields

$$\frac{\delta \langle I_z \rangle}{\langle I_z \rangle} = -\epsilon = -\pi \frac{\omega_1^2}{\dot{\Delta}} \quad (42)$$

an expression which is valid for $\epsilon \ll 1$. By performing n passages, one obtains

$$\frac{\langle I_z \rangle(n)}{\langle I_z \rangle(0)} = (1 - \epsilon)^n \simeq \exp(-n\epsilon) \quad (43)$$

through which one measures ϵ . If the sweep rate $\dot{\Delta}$ is known, this provides [from equation (42)] a calibration of ω_1 , that is of the rf field amplitude. An experimental result for CaF_2 is shown in Figure 3. From the calibration of ω_1 , one obtains a calibration of ξ .

4.2.2 Saturation of Dipolar Energy

A Hamiltonian of the form given by equation (34), at constant Δ , is time independent and the energy associated with it is conserved. If ω_1 is strong enough to ensure a single spin

Figure 3 ^{19}F nuclear polarization in CaF_2 as a function of the number of slightly saturating passages. (Reproduced with permission from Abragam et al.¹³)

temperature in the rotating frame but is so small that the energy term $\omega_1 \langle I_x \rangle$ is negligible, one obtains

$$\Delta \langle I_z \rangle + \langle \mathcal{H}'_D \rangle = \text{constant} \quad (44)$$

or

$$\Delta \frac{d}{dt} \langle I_z \rangle + \frac{d}{dt} \langle \mathcal{H}'_D \rangle = 0 \quad (45)$$

which, according to equation (36), gives

$$\frac{d}{dt} \langle \mathcal{H}'_D \rangle = -\omega_1 \Delta \langle I_y \rangle(\Delta) \quad (46)$$

Under a linear passage through resonance, with a frequency sweep rate $\dot{\Delta}$ so slow that equation (46) remains valid at all times, one obtains

$$\delta \langle \mathcal{H}'_D \rangle = -\frac{\omega_1}{\dot{\Delta}} \int_{-\infty}^{+\infty} \Delta \langle I_y \rangle(\Delta) d\Delta \quad (47)$$

a result which is valid only if $\langle \delta \mathcal{H}'_D \rangle$ is small. What can be measured is the dipolar energy variation corresponding to n passages. Provided the product $\xi \omega_1$ is calibrated as explained above, the experimental results can be connected to the high-temperature linear value

$$\langle \mathcal{H}'_D \rangle = -\beta \text{Tr } \mathcal{H}_D'^2 \quad (48)$$

and thus one obtains a calibrated value of the energy. It makes use of the (nonnormalized) first moment

$$\mathcal{M}_1 = \int_{-\infty}^{+\infty} \Delta \langle I_y \rangle(\Delta) d\Delta \quad (49)$$

and equation (47) becomes

$$\delta \langle \mathcal{H}'_D \rangle = -\frac{\omega_1}{\Delta} \mathcal{M}_1 \quad (50)$$

This result is independent of whether there are several spin species or not. This method has been used to calibrate the dipolar energy in LiH.¹⁸

4.3 First Moment of the Absorption Signal

We return to the first moment as defined by equation (49). This must not be confused with the normalized first moment described in Section 3.2.1. As the absorption signal $I_y(\Delta)$ is the Fourier transform of the (normalized) FID signal [equation (13)], then

$$\begin{aligned} \Delta \langle I_y \rangle(\Delta) &= \frac{\omega_1}{4} \int_{-\infty}^{+\infty} \langle [I_-, I_+(t)] \rangle_0 \Delta \exp(i\Delta t) dt \\ &= -i \frac{\omega_1}{4} \int_{-\infty}^{+\infty} \langle [I_-, I_+(t)] \rangle_0 \frac{d}{dt} [\exp(i\Delta t)] dt \end{aligned} \quad (51)$$

Upon integration by parts over t , and then integration over Δ , one obtains finally¹⁹

$$\mathcal{M}_1 = \frac{\pi}{2} \omega_1 \langle [I_-, [I_+, \mathcal{H}'_D]] \rangle_0 \quad (52)$$

The simplest case is when the system contains only one spin species. Through the commutation relations of spin operators, and the form [equation (24)] of the homonuclear secular dipolar interactions, one obtains

$$\mathcal{M}_1 = 3\pi\omega_1 \langle \mathcal{H}'_D \rangle_0 \quad (53)$$

What is actually measured is

$$\mathcal{M}'_1 = \xi \mathcal{M}_1 = 3\pi\xi\omega_1 \langle \mathcal{H}'_D \rangle_0 \quad (54)$$

The calibration of $\xi\omega_1$ then gives access to a calibrated value of $\langle \mathcal{H}'_D \rangle$.

Consider now the case when there are, say, two spin species I and S . Secular dipolar interactions between unlike spins do not contain flip-flop terms, and it is elementary to show that in such a case

$$\mathcal{M}_1(I) = \pi\omega_1^I \{3\langle \mathcal{H}'_{DII} \rangle_0 + \langle \mathcal{H}'_{DIS} \rangle_0\} \quad (55)$$

and for the spins S signal

$$\mathcal{M}_1(S) = \pi\omega_1^S \{\langle \mathcal{H}'_{DIS} \rangle_0 + 3\langle \mathcal{H}'_{DSS} \rangle_0\} \quad (56)$$

Together with the measurement of the total dipolar energy

$$\langle \mathcal{H}'_{DII} \rangle_0 + \langle \mathcal{H}'_{DIS} \rangle_0 + \langle \mathcal{H}'_{DSS} \rangle_0 \quad (57)$$

by using the saturation method described in the preceding section, it is possible in principle to derive calibrated values for the three partial energies

$$\langle \mathcal{H}'_{DII} \rangle_0, \quad \langle \mathcal{H}'_{DIS} \rangle_0, \quad \langle \mathcal{H}'_{DSS} \rangle_0 \quad (58)$$

4.4 Qualitative Shape of the Absorption Signal

When a spin system, with a single spin species I (for simplicity), is subjected to an ADRF stopped at the distance Δ_0 from resonance, its density matrix is of the form

$$\sigma = \exp[-\beta(\Delta_0 I_z + \mathcal{H}'_D)] / \text{Tr}\{\exp(\dots)\}$$

We assume that $\beta > 0$. If one then looks at the absorption signal $I_y(\Delta)$ with a small, nonsaturating rf field, it can be shown (see Abragam and Goldman,⁶ Chapter 5), that this absorption signal is positive for $\Delta \leq \Delta_0$, vanishes at $\Delta = \Delta_0$, and is negative for $\Delta \geq \Delta_0$. This makes it possible to determine the value of Δ_0 in equation (58), that is the effective field. In the particular case when $\Delta_0 = 0$, it can be shown that the absorption signal is antisymmetric at all spin temperatures

$$\langle I_y \rangle(-\Delta) = -\langle I_y \rangle(\Delta) \quad (59)$$

4.5 Linear Response and Transverse Susceptibility

The transverse susceptibility can be defined through two seemingly different approaches:

1. We wait for the thermal equilibrium when a small (but saturating) rf field is applied at a distance Δ_0 from resonance. This corresponds to a density matrix

$$\sigma_{\text{eq}} = \exp[-\beta(\Delta_0 I_z + \omega_1 I_x + \mathcal{H}'_D)] / \text{Tr}\{\dots\} \quad (60)$$

which yields a transverse spin expectation value

$$\langle I_x \rangle_{\text{eq}} = \chi_{\perp} \omega_1 \quad (61)$$

2. Starting from a density matrix

$$\sigma_{\text{eq}} = \exp[-\beta(\Delta_0 I_z + \mathcal{H}'_D)] / \text{Tr}\{\dots\} \quad (62)$$

we apply a small rf field of amplitude ω_1/γ and look for the dispersion signal at frequency Δ_0

$$\langle I_x \rangle(\Delta_0) = \chi'_{\perp} \omega_1 \quad (63)$$

It can be shown, on the basis of linear response theory, that the two transverse susceptibilities are equal

$$\chi_{\perp} = \chi'_{\perp} \quad (64)$$

The former definition corresponds to the observation of dispersion during a fast passage (slow enough for the system to be at all times infinitely close to equilibrium, but fast enough for spin–lattice relaxation to be negligible). For the second definition, it is not necessary to look at the dispersion signal.

Instead, one can observe the absorption signal $\langle I_y \rangle(\Delta)$ and compute the dispersion $\langle I_x \rangle(\Delta_0)$ from the Kramers–Kronig relation¹

$$\langle I_x \rangle(\Delta_0) = -\frac{1}{\pi} \mathcal{P} \int_{-\infty}^{+\infty} \frac{\langle I_y \rangle(\Delta) d\Delta}{\Delta - \Delta_0} \quad (65)$$

Since the absorption signal is calibrated, as shown above, this method yields a calibrated value for the transverse susceptibility.

4.6 Cotanh Transform of the Absorption Signal: Measurement of the Dipolar Temperature

The cotanh transform is one form of the fluctuation–dissipation theorem,²⁰ as applied to the absorption signal.¹⁸ For a system demagnetized to the distance Δ_0 from the spins I resonance, i.e. for a single spin system, when its density matrix is of the form given by equation (62), the cotanh transform (a neologism) is formally defined by

$$\mathcal{C}(\beta) = \int_{-\infty}^{+\infty} \langle I_y \rangle(\Delta) \coth \left[\frac{\beta}{2} (\Delta - \Delta_0) \right] d\Delta \quad (66)$$

where $\langle I_y \rangle(\Delta)$ is the absorption signal.

It can be shown that

$$\mathcal{C}(\beta) = -\pi \omega_1 \langle I_x^2 + I_y^2 \rangle_0 \quad (67)$$

This property is valid even when there are several spin species. It can be used when, besides the abundant spins, the system also contains a spin species in low abundance (for instance ^{43}Ca in CaF_2). It is these spins that we call I . Since, for example,

$$I_x = \sum_i I_x^i \quad (68)$$

is the sum of all individual spin components, we have

$$\langle I_x^2 \rangle_0 = \sum_i \langle I_x^{i2} \rangle_0 + \sum_{i \neq j} \langle I_x^i I_x^j \rangle_0 \quad (69)$$

For low-abundance spins, their relative distance is large, on average, so that

$$\langle I_x^i I_x^j \rangle_0 \simeq \langle I_x^i \rangle_0 \langle I_x^j \rangle_0 \quad (i \neq j) \quad (70)$$

which vanishes when the spins I are not purposely given a transverse polarization. One is then left with

$$\langle I_x^2 \rangle_0 + \langle I_y^2 \rangle_0 \simeq \sum_i \langle I_x^{i2} + I_y^{i2} \rangle_0 = \sum_i [I(I+1) - \langle I_z^{i2} \rangle_0] \quad (71)$$

In the presence of N_I equivalent spins I , one then has

$$\mathcal{C}(\beta) = -N_I \pi \omega_1 [I(I+1) - \langle I_z^2 \rangle_0] \quad (72)$$

In the case when nuclear alignment is negligible

$$\langle I_z^2 \rangle_0 = \frac{1}{3} I(I+1) \quad (73)$$

and one finally obtains

$$\mathcal{C}(\beta) \simeq -\frac{2}{3} N_I \pi \omega_1 I(I+1) \quad (74)$$

Using calibrated absorption signals, one adjusts by trial-and-error the value of β in equation (66) so as to satisfy equation (74). This yields a calibrated value of the spin temperature β^{-1} .

5 NONLINEAR EFFECTS IN SPIN TEMPERATURE

Consider, for simplicity, a system with only one spin species, subjected to Zeeman and dipolar interactions. At high field, there are two constants of the motion: the Zeeman energy $\omega_0 I_z$ and the secular dipolar energy $\langle \mathcal{H}'_D \rangle$. Internal equilibrium corresponds to the most probable state, i.e. that which maximizes the entropy

$$S = -k_B \text{Tr}\{\sigma \ln \sigma\} \quad (75)$$

where σ is the spin density matrix, and is consistent with the conservation of the above-mentioned quantities. This corresponds to a density matrix of the form

$$\sigma = \exp(-\beta_Z \omega_0 I_z - \beta \mathcal{H}'_D) / \text{Tr}\{\exp(\dots)\} \quad (76)$$

where β_Z and β are the Zeeman and dipolar inverse temperatures, respectively. If we introduce the partition function

$$\mathcal{Z}(\beta_Z, \beta) = \text{Tr}\{\exp(-\beta_Z \omega_0 I_z - \beta \mathcal{H}'_D)\} \quad (77)$$

we have

$$\omega_0 \langle I_z \rangle = \omega_0 \text{Tr}\{\sigma I_z\} = -\frac{\partial}{\partial \beta_Z} \ln \mathcal{Z} \quad (78)$$

$$\langle \mathcal{H}'_D \rangle = \text{Tr}\{\sigma \mathcal{H}'_D\} = -\frac{\partial}{\partial \beta} \ln \mathcal{Z} \quad (79)$$

At high temperature, that is to first order with respect to the inverse spin temperature, one obtains the well-known result

$$\omega_0 \langle I_z \rangle = -\beta_Z \omega_0^2 \text{Tr}\{I_z^2\} \quad (80a)$$

$$\langle \mathcal{H}'_D \rangle = -\beta \text{Tr}\{\mathcal{H}'_D^2\} \quad (80b)$$

At lower temperature, both $\omega_0 \langle I_z \rangle$ and $\langle \mathcal{H}'_D \rangle$ depend, in a complicated way, on both inverse temperatures, β_Z and β . All the problems arise from the term in $\mathcal{H}'_D$. If β is zero, that is there is purely Zeeman order, it is elementary to calculate all steady-state expectation values of interest (as seen above, calculating a dynamic quantity such as the FID remains a formidable task). We describe a perturbative approach in which one calculates the physical quantities to all orders with respect

to the inverse Zeeman temperature β_Z , but in the form of a power expansion in dipolar inverse temperature β (it will be shown that, in fact, we can achieve slightly more than that). For secular dipolar interactions, and especially for spins $\frac{1}{2}$, the most convenient approach is through the diagrammatic method devised by Stinchcombe et al.^{21,22} The method is not described in detail here. Suffice it to say that the diagram contains bonds, associated with dipolar interaction coefficients, and vertices, the values of which depend on the inverse Zeeman temperature. More precisely, for spins $\frac{1}{2}$, the values depend on

$$t = \tanh(-\frac{1}{2}\beta_Z\omega_0) \quad (81)$$

By differentiating equations (78) and (79) with respect to β and with respect to β_Z , respectively, we obtain

$$\frac{\partial}{\partial\beta}\omega_0\langle I_z \rangle = \frac{\partial}{\partial\beta_Z}\langle \mathcal{H}'_D \rangle \quad (82)$$

whence

$$\omega_0\langle I_z \rangle(\beta_Z, \beta) = \omega_0\langle I_z \rangle(\beta_Z, 0) + \int_0^\beta \frac{\partial}{\partial\beta_Z}\langle \mathcal{H}'_D \rangle(\beta_Z, \lambda) d\lambda \quad (83)$$

This enables one to calculate $\langle I_z \rangle$ as a power expansion in β from the corresponding expansion for $\langle \mathcal{H}'_D \rangle$. One can also obtain β -expansion formulas for the entropy, free energy, etc.

There is an advantage in using this approach for systems where the spins experience a longitudinal average field, that is when, in equation (24)

$$\frac{\gamma^2\hbar}{2} \sum_j \frac{1 - 3\cos^2\theta_{ij}}{r_{ij}^3} = q \neq 0 \quad (84)$$

a value which is equal for all spins i .

It can be proved that, in such a case, all vertices can be 'renormalized' in such a way that:

1. one considers only diagrams with no free ends; and
2. in each vertex, the term t in equation (81) is replaced by

$$t' = \tanh(-\frac{1}{2}\beta_Z\omega_0 - \frac{1}{2}\beta qt) \quad (85)$$

For a given physical quantity, the term of zero order corresponds to the mean-field approximation, and the terms in increasing powers of β correspond to the contributions of short-range correlations of increasing order.

We present below several experimental illustrations of nonlinear effects in spin temperature, for ^{19}F spins in spherical samples of CaF_2 ($q = 0$), together with the theoretical predictions from expansions up to β^3 .

5.1 Dipolar Energy versus Polarization in High Effective Field

The experiment consists of measuring $\langle \mathcal{H}'_D \rangle$ as a function of polarization p in a system having a density matrix

$$\sigma = \exp[-\beta(\Delta_0 I_z + \mathcal{H}'_D)] / \text{Tr}\{\dots\} \quad (86)$$

Figure 4 Non-Zeeman energy per fluorine spin as a function of nuclear polarization, in a spherical sample of CaF_2 at thermal equilibrium in the rotating frame in an effective field of 7.12 G· $\mathbf{B}_0 \parallel [100]$ and $T > 0$. Curves 1 and 2: first- and third-order approximations with dipolar interactions only. Curve 3: after addition of an adjusted contribution from impurities. (Reproduced with permission from Goldman et al.²³)

Figure 5 Transverse susceptibility of ^{19}F in a spherical sample of CaF_2 in zero effective field, against dipolar energy, together with first- and third-order approximations. Conditions: $\mathbf{B}_0 \parallel [100]$, $T < 0$. (Reproduced with permission from Goldman et al.²³)

in the case when Δ_0 is much larger than the local frequency D . When limited to the first order in β , the theoretical expression is

$$\langle \mathcal{H}'_D \rangle = \frac{N}{4} \frac{D^2}{\Delta_0} \ln \left(\frac{1+p}{1-p} \right) \times (1-p^2) \left(1 - \frac{2}{3} p^2 \right) \quad (87)$$

where β is expressed as a function of p .

Figure 6 Longitudinal susceptibility of ^{19}F in the same sample and under the same conditions as in Figure 5. (Reproduced with permission from Goldman et al.²³)

Experimentally, one measures the loss of polarization resulting from a sudden rf irradiation at Δ_0 from resonance, starting from a state of pure Zeeman order. Figure 4 shows that agreement with theory requires the addition of an extra term to the secular dipolar reservoir.²³ The extra term has been identified as originating in the random field distribution due to the presence of paramagnetic impurities.

5.2 Transverse and Longitudinal Susceptibilities

Figures 5 and 6 show the transverse and longitudinal susceptibilities in zero effective field as a function of the dipolar energy,²³ together with the theoretical expectation from expansions up to β^3 . The experimental method²³ used to obtain these two figures is rather complicated and is not described here. As can be seen in Figures 5 and 6, the results depart markedly from theory at dipolar energies per spin above about 2 kHz. This is no accident: these experiments were part of a general study of nuclear magnetic ordering and, as confirmed by other observations, the departures coincide with the onset of nuclear antiferromagnetism—but that is another story.

1 INTRODUCTION

Efficient algorithms for computing the discrete Fourier transform (DFT) served as one of the enabling technologies behind the development of modern NMR spectroscopy.¹ While use of the fast Fourier transform (FFT) was widespread in science and engineering in the 1960s, it was nevertheless a fairly audacious proposal in 1965 to use the FFT to analyze time domain data as an alternative to conventional field or frequency swept experiments, since the marriage of a computer capable of performing the FFT to an NMR spectrometer had yet to be consummated. The implications turned out to be profound, of course, opening the way to the development of multidimensional NMR and magnetic resonance imaging. Yet while providing a crucial capability, the DFT is not without inherent limitations, some of which can be avoided by the use of alternative methods that would have been impractical in 1965, or even as recently as 1990.

2 LIMITATIONS OF THE DFT

The reasons for using the DFT are compelling, beyond even the efficiency of FFT algorithms. Among them are the linearity of the DFT (which simplifies quantification and error analysis and also permits applications such as difference spectroscopy) and the full weight of the theory behind the continuous Fourier transform.² A time series can be characterized as a finite sum of periodic functions, given by the inverse DFT

$$d_k = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} f_n e^{2\pi i k n / N} \quad (1)$$

where d_k is the value of the time series at time $k \Delta T$, ΔT is the interval between samples, f_n is the coefficient of the Fourier

component with frequency $n/N \Delta T$, and N is the number of Fourier components (which is equal to the number of samples in the time series). The Fourier coefficients are computed by the forward DFT

$$f_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} d_k e^{-2\pi i k n / N} \quad (2)$$

Differences between the DFT and the continuous Fourier transform result from sampling and truncation, in both time and frequency. Sampling in the time domain can introduce artifacts in the spectrum, in which components with frequencies greater than $1/\Delta T$ appear at lower frequencies (aliasing). Truncation in the time domain introduces spurious spread of the components in the spectrum (leakage). Characterization of a time series beyond the sampled interval by means of Fourier coefficients computed from the interval (which is equivalent to estimating the spectrum with a digital resolution higher than $1/N \Delta T$) is correct only for periodic time series, since each Fourier component in equation (1) satisfies $e^{2\pi i k n / N} = e^{2\pi i (k+N)n / N}$.

Another difficulty associated with the DFT stems from the relationship between the number of data samples and the digital frequency resolution. The term digital frequency resolution is used to refer to the frequency difference between adjacent points in a discrete spectral estimate, and it should be distinguished from the resolution of the spectral estimate, which is a measure of the ability of a spectral estimate to distinguish between closely spaced frequency components. The digital resolution places a lower bound on the resolution of a spectral estimate. The spacing between points in the frequency domain is given by $1/N \Delta T$; therefore, to achieve high digital frequency resolution it is desirable to collect as long a data record as possible. In pulsed NMR experiments, however, the signal of interest usually diminishes with time. Thus collecting long data records to improve resolution rapidly leads to diminishing returns by degrading the signal-to-noise ratio (S/N) of the resulting spectrum. A technique for overcoming this degradation is to collect data for a short period of time and then append zeroes to the end (zero filling). This process also introduces discontinuities into the time series, resulting in leakage. The leakage can be severe if the signal of interest has not decayed sufficiently before the end of the sampled interval. Weighting functions (also referred to as apodization, window, or taper functions) can be applied to the time data, to minimize the extent of leakage by reducing the intensity of the signal near the end of the sampled interval, although this generally incurs an accompanying loss of resolution due to broadening of the spectral components. A virtual zoo of weighting functions exists, each function fulfilling a different goal (leakage reduction, resolution enhancement, sensitivity enhancement) or striking a compromise between various goals.³ In particular the matched filter (which mimics the decay of the FID envelope), because of its theoretical properties, has long been employed to enhance sensitivity.⁴

One way to extend a time series in a more intelligent fashion than appending zeroes, is to extrapolate using linear prediction. Linear prediction is based on a model in which each value of a time series is assumed to be a linear combination of the preceding values. However, linear prediction is not

always appropriate. It is strictly correct only for exponentially decaying sinusoids, it requires a relatively high S/N, and it is only applicable to time series that have been sampled at uniform intervals. (See *Fourier Transform and Linear Prediction Methods*.)

3 SPECTRUM ANALYSIS AS AN INVERSE PROBLEM

A more general approach, that avoids the limitations of the DFT and linear prediction, treats spectrum analysis of a time series as an inverse problem. Inverse problems are those in which the properties of interest can only be viewed indirectly. A famous example is Plato's allegory of the cave,⁵ in which the problem is to infer the characteristics of an object from the shadows in the firelight it casts on the walls of a cave. In NMR spectrum analysis, the inverse problem can be stated as that of recovering the spectrum f_n of an ensemble of spins, when the only observations we have are the FID at various times (d_k), contaminated by noise (ϵ_k):

$$\hat{d}_k = d_k + \epsilon_k \quad (3)$$

We can approach this inverse problem by placing restrictions on the possible solutions f_n . The first restriction comes from the obvious requirement that f_n must be consistent with the experimental observations. The agreement can be quantified through the use of a constraint statistic that measures how well the reconstructed spectrum agrees with the available data. The statistic is determined by comparing a 'mock' FID, given by the inverse DFT of the reconstructed spectrum, with the actual data. When the noise and experimental error in the measured data are normally distributed, an appropriate statistic is the (unweighted) χ^2 statistic,

$$\chi^2 = \sum_{k=0}^{M-1} |m_k - \hat{d}_k|^2 \quad (4)$$

where M is the number of data samples collected, and m_k is the mock FID. Other forms of the constraint statistic, C , are possible, but χ^2 is the one generally used, because of its simplicity and the difficulty in justifying any other distribution of errors in the data. (A weighted χ^2 statistic can also be used, for example, if there is good reason to believe that some of the data points are more subject to error than others.) Whatever the form of C , the constraint that the reconstructed spectrum must be consistent with the measured data takes the form

$$C \leq C_0 \quad (5)$$

where C_0 is an upper bound on the allowed error. Given a prior estimate of the amount of noise in the data, C_0 should be comparable to the root-mean-square (RMS) noise level.

4 SOLVING THE INVERSE PROBLEM USING MAXIMUM ENTROPY RECONSTRUCTION

The constraint statistic alone does not provide enough of a restriction on the possible reconstructions to be of much use.

In fact, any mock FID that matches the experimental FID to within C_0 for the first M points will satisfy the constraint. If we are to improve over the DFT, we need some additional criteria for regularizing the reconstructed spectrum, that will effectively constrain the values of the mock FID beyond M . One such criterion is the maximum entropy principle, which says that a reasonable reconstruction should add no new information beyond that contained in the experimental data. The principle originated in the work of Claude Shannon on the information-carrying capacity of circuits,⁶ where he showed that the entropy of a probability distribution p , defined by

$$S(p) = - \sum_n p_n \log p_n \quad (6)$$

is a measure of the lack of information. There is a formal link between Shannon's entropy and the statistical entropy of an ensemble, and this link can be used to provide a constraint on possible spectrum reconstructions. On a more pragmatic level, the maximum entropy principle can be viewed simply as a means of obtaining a smooth, bounded reconstruction. The use of the maximum entropy principle to regularize the possible solutions to the spectrum analysis inverse problem is called maximum entropy (MaxEnt) reconstruction. [Maximum entropy reconstruction should be distinguished from the maximum entropy method (MEM) introduced by Burg,⁷ which is more closely related to linear prediction.] Entropy is not unique as a regularizer, however, and there are other functionals that have similar properties.⁸

An important distinction between MaxEnt reconstruction and methods of spectrum analysis (such as those based on linear prediction) that implicitly assume Lorentzian lineshapes, is that MaxEnt reconstruction per se makes no assumptions about the signal to be recovered. Yet it is flexible enough to allow prior information to be incorporated into the reconstruction. A particularly simple means for incorporating prior knowledge is through a convolution kernel. Typical kernels might include exponential decay at some known rate, or J modulation at a known frequency. The reconstruction then yields the *deconvolved* spectrum having the highest entropy.

5 NUMERICAL ALGORITHM

The maximum entropy principle provides a formal basis for reconstructing the spectrum f_n , but some additional details must be addressed in order to apply MaxEnt reconstruction to NMR data. For modern NMR experiments, we need to be able to reconstruct complex spectra containing both positive and negative components. The Shannon formula [equation (6)] clearly does not apply to complex-valued spectra. A more suitable approach is to find the spectrum corresponding to a maximum entropy ensemble of spin- $\frac{1}{2}$ particles.⁹ The resulting formula is

$$S(f) = - \sum_{n=0}^{N-1} \frac{|f_n|}{def} \log \left(\frac{|f_n|/def + \sqrt{4 + |f_n|^2/def^2}}{2} \right) - \sqrt{4 + |f_n|^2/def^2} \quad (7)$$

where def is a scale factor. The maximum entropy distribution prescribes the value of def (it depends on the spectrometer

response and the total number of spins in the sample). However, it is more convenient to treat def as an adjustable parameter.

The next detail that we are faced with is how to solve the constrained optimization problem, that is, the problem of maximizing $S(f)$ subject to the constraint that $C \leq C_0$. An equivalent unconstrained optimization problem is to maximize the objective function

$$Q = S - \lambda C \quad (8)$$

where λ is a Lagrange multiplier. The solution we seek corresponds to a critical point of Q , i.e., a point where $\nabla Q = 0$. In the general case there is no analytic solution to this problem, and we are forced to seek numerical solutions. For many problems of this type, a numerical search using the gradient of the objective function (steepest ascent or conjugate gradients) is a reasonably efficient method for finding the critical point. Unfortunately, an objective function constructed from two such dissimilar functionals as the χ^2 statistic and the entropy is quite difficult to maximize. Practical solution of the general MaxEnt reconstruction problem requires a fairly complex optimizer, and the most efficient algorithms require of the order of 100 (or more) times the computational effort of the FFT.

Since the entropy [given by equation (7)] and the constraint statistic [equation (4)] are both everywhere convex, there is a unique, global solution to the constrained optimization problem. Furthermore, this maximum satisfies $C = C_0$ provided that the trivial solution $f_n = 0$ does not also satisfy the constraint.

There have been several algorithms published for computing MaxEnt reconstructions. A particularly robust and efficient algorithm was described by Skilling and Bryan.¹⁰ This method uses multiple search directions and a variable metric to determine the size of the step at each iteration. We describe here a variant we have found useful in our laboratory.

The algorithm begins with a flat trial spectrum equal to zero everywhere. At each iteration, a mock FID is computed from the current value of the trial spectrum. In the general case this involves inverse Fourier transformation and multiplication by a decay kernel, which is specified by the user as an input parameter. A decay does not need to be applied, but when it is, the reconstructed spectrum is an approximation of what would have been observed had the decay not been present. The first M points of the N point mock FID are used to compute the value of C , according to equation (4). The algorithm constructs a small set of direction vectors, and computes a quadratic approximation to the entropy in the subspace spanned by these vectors. Since the constraint is itself quadratic, it is possible to maximize analytically the entropy approximation subject to the constraint in this subspace. This results in the trial spectrum for the next iteration.

The quadratic approximation to the entropy is accurate only for small step sizes, so when the value of C for the mock FID is far from the desired value C_0 , it is better to solve the analytic maximization using a constraint value C' , intermediate between C_0 and the current value of C , rather than attempt one large step. Consequently the algorithm proceeds in two phases. In the first phase, C is larger than C_0 and the algorithm attempts to lower C . In the second phase, C_0 has been attained and the algorithm seeks to maximize the entropy.

This approach could be based on direction vectors that include ∇S , the gradient of the entropy (with respect to f). The problem is that the gradient can be dominated by small values of f , and the algorithm would spend more time adjusting values that are close to zero than adjusting signal peaks. The key insight of Skilling and Bryan was that the introduction of an 'entropy metric' produces an algorithm that more evenly weights the contributions of large and small values of the spectrum. Using the entropy metric amounts to replacing ∇S and ∇C (the gradient of the constraint with respect to the trial spectrum) with $\mathbf{H}^{-1}\nabla S$ and $\mathbf{H}^{-1}\nabla C$, where $\mathbf{H}$ is $-\nabla^2 S$, the negative of the Hessian (the matrix of second derivatives) of S . The matrix $\mathbf{H}$ is nearly diagonal, so its inverse is easy to compute. The search directions used during the first phase of the algorithm are:

$$\begin{aligned} \nabla C \\ \mathbf{H}^{-1}\nabla C \\ \mathbf{H}^{-1}\nabla Q \\ \mathbf{H}^{-1}(\nabla^2 C)\mathbf{H}^{-1}\nabla Q \\ Q = S - \lambda C \end{aligned} \quad (9)$$

and λ is set to $|\nabla S|/|\nabla C|$. During the second phase, the second search direction is replaced by ∇Q . In the original algorithm of Skilling and Bryan, neither ∇C nor ∇Q are used as search directions. We found that including them speeds convergence. The major effort in computing these vectors stems from four discrete Fourier transformations (two each to compute ∇C and to apply $\nabla^2 C$) and multiplication by $\mathbf{H}^{-1}$.

With these direction vectors, a quadratic model for the entropy and the constraint can be constructed using a second-order Taylor expansion about the trial spectrum. A spectrum f' in the subspace spanned by the direction vectors can be represented by a vector of length four, $\bar{a}$; the correspondence is given by

$$f' = a_1 v_1 + a_2 v_2 + a_3 v_3 + a_4 v_4 + f_0 \quad (10)$$

where v_1 through v_4 are the direction vectors and f_0 is the current trial spectrum. The quadratic approximations then become

$$S(\bar{a}) \approx S(f_0) + \bar{B} \cdot \bar{a} + \frac{1}{2} \bar{a} \cdot \mathbf{M} \cdot \bar{a} \quad (11a)$$

and

$$C(\bar{a}) \approx C(f_0) + \bar{G} \cdot \bar{a} + \frac{1}{2} \bar{a} \cdot \mathbf{N} \cdot \bar{a} \quad (11b)$$

where vectors $\bar{B}$ and $\bar{G}$ are inner products of ∇C and ∇S with the direction vectors

$$\bar{B}_i = \nabla S \cdot v_i \quad (12a)$$

$$\bar{G}_i = \nabla C \cdot v_i \quad (12b)$$

Similarly, the 4×4 matrices $\mathbf{M}$ and $\mathbf{N}$ are the inner products of $\nabla^2 S$ and $\nabla^2 C$ with the direction vectors:

$$M_{ij} = v_i \cdot \nabla^2 S \cdot v_j \quad (13a)$$

$$N_{ij} = v_i \cdot \nabla^2 C \cdot v_j \quad (13b)$$

Computing these values requires several more Fourier transformations and large matrix products. The Lagrange condition $\nabla S - \lambda \nabla C = 0$ for the maximum of the objective function in the subspace becomes

$$(\bar{B} + \mathbf{M} \cdot \bar{a}) - \lambda(\bar{G} + \mathbf{N} \cdot \bar{a}) = \bar{0} \quad (14)$$

By a suitable change of coordinates in the subspace it is possible to simplify this equation by simultaneously diagonalizing $\mathbf{M}$ and $\mathbf{N}$. The solution then is given by

$$a_i = \frac{B_i - \lambda G_i}{\lambda N_{ii} - M_{ii}} \quad (15)$$

λ can be found by using a binary search to determine the value for which $C(\bar{a})$ equals the target value C' .

Convergence criteria for determining when the trial spectrum is sufficiently close to the MaxEnt reconstruction derive from the Lagrange condition and the requirement that $C \approx C_0$. The Lagrange condition implies that ∇C and ∇S are parallel, so convergence can be monitored by computing the value

$$Test = \left| \frac{\nabla S}{|\nabla S|} - \frac{\nabla C}{|\nabla C|} \right| \quad (16)$$

The algorithm terminates when $C \approx C_0$ and $Test \ll 1$. In practice, we stop the algorithm when $Test < 10^{-3}$, or when a preset maximum number of iterations has been executed.

The value of C_0 can be estimated from the data by examining a portion of an FID that is essentially free of signal, or alternatively, by examining a signal-free region of the DFT spectrum. For MaxEnt reconstructions, C_0 should generally be somewhat larger than the estimate of the RMS noise level. Very large values of C_0 result in overly smooth reconstructions in which weaker components are washed out.

The other adjustable parameter, def , is rather more difficult to prescribe. def represents the scale at which the nonlinear effects of MaxEnt reconstruction become significant. A large value of def results in nearly linear reconstructions. When def is large and C_0 is zero, the resulting reconstruction is essentially the same as the DFT of the zero-filled FID. However, very low values of def can give rise to spurious artifacts. As a rule of thumb, we use values of def somewhat lower than the noise level. Fortunately, the results are not overly sensitive to the choice of def . We know of no algorithmic procedure for determining the best value.

6 ANALYTIC SOLUTION

While numerical solution is required in the general case, there is a special case of MaxEnt reconstruction that has an analytical solution. Though unrealistic in several respects, examination of this special case can give some insights into how MaxEnt reconstruction works. When N (the number of points in the reconstructed spectrum) is equal to M (the number of experimental data points), and when the relationship between the trial spectrum and the mock FID is given simply by the inverse Fourier transform (i.e. we are not trying to deconvolve a decay), the solution can be found analytically.

Parseval's theorem, which states that the sum of the squared magnitudes of a vector is equal to the sum of the squared magnitudes of its Fourier coefficients, permits the constraint statistic to be computed in the frequency domain. Under these circumstances the Lagrange condition becomes

$$0 = \nabla Q = \nabla S - 2\lambda(f - F) \quad (17)$$

where F is the DFT of the data $\hat{d}$. The solution is given by

$$|f_n| = \delta_\lambda^{-1}(|F_n|) \quad (18a)$$

$$\text{phase}(f_n) = \text{phase}(F_n) \quad (18b)$$

where δ_λ is the function

$$\delta_\lambda(x) = x - s'(x)/2\lambda \quad (19)$$

and $s(x)$ is the contribution of a spectral component with magnitude x to the overall entropy S [see equation (7)]. This result corresponds to a nonlinear transformation, applied point by point to the DFT of the time domain data. The transformation depends on the value of λ , and has the effect of scaling every point in the spectrum down, but points closer to the baseline are scaled down more than points far above the baseline. Figure 1 illustrates $\delta_\lambda^{-1}(x)$ for various values of λ . As λ increases, the relative weight given to the constraint term in the objective function increases, and the transformation becomes more nearly linear.

This helps to explain the characteristic of MaxEnt reconstructions that noise near the baseline is suppressed more than noise away from the baseline (for example, superimposed on a broad peak). A further point to note is that there is a very important distinction between S/N and sensitivity. Sensitivity is the ability to distinguish signal from noise. Applying the same transformation to both the signal and the noise cannot improve this ability, since peaks that are comparable in height to the noise level will be reduced by the same amount as the noise. The ratio between the highest signal peaks and the noise

Figure 1 The nonlinear transformation $\delta_\lambda^{-1}(x)$ applied to the DFT spectrum that results in the MaxEnt reconstruction when $N = M$, for various values of the Lagrange multiplier λ .

may increase, but small peaks will be just as difficult to distinguish as before. For linear operations (such as apodization), an improvement in S/N necessarily implies an improvement in sensitivity; for nonlinear operations (such as MaxEnt reconstruction) this is not so. In this special case, gains in S/N in the MaxEnt reconstruction are purely cosmetic. In the more general case, for example when an approximately known decay is deconvolved from the reconstructed spectrum, there may be real sensitivity gains. However, a prudent investigator will always question whether gains in S/N really correspond to gains in sensitivity.¹¹

7 EXAMPLE APPLICATIONS

Armed with an efficient optimizer, the Cambridge Maximum Entropy group and their collaborators performed the earliest applications of MaxEnt reconstruction to NMR.¹² Properties of MaxEnt reconstruction depend on both the data and the parameters of the reconstruction, such as the decay kernel, and so are best illustrated by examples using typical NMR data. In addition to providing a concrete means of exploring the use of MaxEnt reconstruction for improving resolution or enhancing sensitivity, they provide a means of comparing the performance of alternate methods.

7.1 One-Dimensional

7.1.1 Resolution

Figure 2 illustrates the methyl and aliphatic region of spectra obtained for a sample of 20 mM L-Ala-L-Pro in D₂O at pD 6.0 and 25°C. Data consisting of 1024 complex points were collected at 400 MHz on a JEOL GX-400 spectrometer. Shown are the zero-filled (to 8192 points) DFT spectrum without (a) and with (b) windowing (60°-shifted sine-bell). Figure 2(c) is the DFT spectrum obtained by extrapolating from 1024 points to 8192 with linear prediction, using a filter order of 60 and reflecting roots of the characteristic polynomial that fall outside the unit circle to the inside. Figure 2(d) illustrates the MaxEnt reconstruction, computed using 1.0 for C_0 and 0.1 for def . All parts of Figure 2 are plotted using the same scale. The region near the methyl peaks (around 1.55 ppm, arising from both the *cis* and *trans* forms of the peptide bond) shows the artifacts due to truncation. Windowing the FID ameliorates the artifacts, at the expense of lower resolution due to broadening. More aggressive resolution enhancement (for example a 30°-shifted sine-bell) improves the resolution at the expense of more pronounced negative 'wings' surrounding the methyl peaks. Extrapolation by linear prediction [Figure 2(c)] dampens the artifacts somewhat; further reduction could be obtained by windowing the extrapolated FID. The MaxEnt reconstruction [Figure 2(d)] is virtually free of artifacts and has narrow lines; further line narrowing could be achieved by deconvolving the natural linewidth.

7.1.2 Signal-To-Noise Ratio

Figure 3 illustrates gains in S/N that can be achieved using MaxEnt reconstruction. Figure 3(a) contains the aliphatic

Figure 2 Aliphatic region of the ¹H spectrum of L-Ala-L-Pro, from 1024-point data: (a) zero filled to 8192 and Fourier transformed; (b) zero filled, apodized using a 60°-shifted sine-bell and Fourier transformed; (c) extrapolated to 8192 points using linear prediction and Fourier transformed; (d) MaxEnt reconstruction

region of the DFT spectrum for a sample of 0.1% ethylbenzene in deuteriochloroform, using a single 90° observe pulse; 1024 complex points were zero-filled to 4096 and windowed using a 60°-shifted sine-bell prior to Fourier transformation. Figure 3(b) shows the DFT spectrum of data collected using a 7° observe pulse, and processed as in Figure 3(a). Figure 3(c) shows the MaxEnt reconstruction obtained using 2.8 for C_0 and 0.01 for def ; no decay was deconvolved. Although striking, the improvement in S/N does not necessarily correspond to a real gain in sensitivity, as discussed earlier. Note that the multiplet structure of the peak near 3.25 ppm is not much more evident in (c) than in (b).

7.1.3 Robustness

A characteristic of MaxEnt reconstruction that distinguishes it from parametric methods, such as linear prediction, is that it makes no implicit assumptions about the nature of the data (although using MaxEnt reconstruction to perform deconvolution does presume the convolution kernel to be correct). Linear prediction, however, is strictly correct only for exponentially decaying sinusoids. MaxEnt is thus less

Figure 3 Aliphatic region of the ^1H spectrum of ethylbenzene: (a) obtained using a 90° observe pulse; (b) obtained using a 7° observe pulse followed by 60° -shifted sine-bell apodization, zero filling, and Fourier transformation; (c) obtained using a 7° observe pulse followed by MaxEnt reconstruction

susceptible to bias when the signal has unusual characteristics such as markedly nonexponential decay, when the S/N is low, or when the data have been corrupted. It is quite common for points at the beginning of a FID to be corrupted, which can result in distorted baselines. In these circumstances, backwards linear prediction can be used to correct the corrupted points. However, if the corrupted data points are in the middle of a FID, or distributed in some unusual fashion throughout the FID, linear prediction is less useful. MaxEnt reconstruction, however, does not require the data to be sampled at uniformly spaced intervals, and so can be applied quite easily to data that are corrupted in an irregular fashion. It is our own sad experience that points in the indirect dimensions of long multidimensional experiments are occasionally contaminated by intermittent instrument failure or environmental influences. Maximum entropy reconstruction provides a means of recovering useful spectra from such data.

To demonstrate the possibilities, we consider a contrived example, constructed by manually corrupting the one-dimensional FID used to generate Figure 3(a). The complex 1024-point FID was corrupted by setting to zero the real and imaginary parts of the points from 350 to 359 and 750 to 759. Figure 4(a) shows the DFT spectrum of the corrupted FID, zero-filled to 4096 points. Figure 4(b) and (c) are 4096-point MaxEnt reconstructions, using 1.0 for C_0 and 0.1 for def , and without deconvolving a decay. In Figure 4(b) all 1024 points of the FID were included in the computation of χ^2 , while in Figure 4(c) the corrupted points were left out. Figure 4(b) illustrates that MaxEnt reconstruction is much more robust to

Figure 4 Spectra computed from data corrupted at two interior stretches of the FID using: (a) Fourier transformation, (b) MaxEnt reconstruction utilizing the entire data set, and (c) MaxEnt reconstruction excluding the corrupted data points

data contamination than the DFT. Figure 4(c) shows the flexibility of MaxEnt reconstruction for treating data corrupted at arbitrary locations when the points of corruption are known.

7.2 Multidimensional

Maximum entropy reconstruction can also be applied to multidimensional data, and it is here that the ability to obtain high-resolution spectra from short data records offers the most significant benefits. Since the data collection time increases linearly with the amount of data collected in indirect dimensions of a multidimensional data set, resolution in these dimensions is often limited by practical considerations of the amount of experiment time available. An advantage of MaxEnt reconstruction over linear prediction for ameliorating those constraints is that the data samples need not be collected at uniform intervals, allowing data collection to be tailored to the type of experiment, sampling more frequently when the S/N is high and hence making more efficient use of available measuring time.

There are a number of ways MaxEnt reconstruction can be extended to multiple dimensions. The most general is simply to compute the entropy of the entire spectrum. As a practical matter, however, this can present a formidable computational challenge for large data sets, since each iteration of the reconstruction algorithm requires several transformations from the time to the frequency domain (and back). An alternative that is far less demanding is to apply MaxEnt reconstruction to each FID in one dimension independently. With this approach, MaxEnt reconstructions of large multidimensional data sets

can be performed efficiently on typical workstations. With a small modification to the algorithm, this approach using a series of one-dimensional reconstructions yields results that are nearly equivalent to the more general multidimensional reconstruction.

In one-dimensional MaxEnt reconstruction, one seeks the local maximum of the objective function for which $C = C_0$. This occurs for a specific value of λ . When computing MaxEnt reconstruction for the rows of a multidimensional data set, normal variations in the noise and the signal can result in different values of λ for each row. The consequences of this variation are often insignificant, but they can be important if they are large enough to perturb the lineshapes, or if quantification of the reconstructed spectrum is performed. Since the nonlinearity of MaxEnt reconstruction depends on the relative weights applied to the entropy and the constraint statistic, it is important to ensure that the same weight (value of λ) applies to each row. This is relatively easy to accomplish by choosing a typical row, estimating the noise, and computing a normal one-dimensional MaxEnt reconstruction. For the multidimensional data set, each row is then reconstructed using the value of λ obtained from the reconstruction of the trial row, instead of iterating to achieve $C = C_0$.

While the resolution of a spectrum determined by MaxEnt reconstruction is mainly determined by the time of the last data sample (as for the DFT), higher sensitivity for the same number of measurements can be achieved by tailoring the sampling schedule to the expected signal.^{13–15} The optimal schedule depends on whether the signal is an exponentially damped sinusoid, is cosine modulated, or is stationary (such as that in a constant time experiment).

Figure 5 shows the methyl region of the two-dimensional ^1H – ^{13}C HMQC spectra for a 10 mM sample of the 16-residue peptide $\alpha_1\text{B}$ in D_2O at pH 5.0 and 25°C , obtained with natural abundance of ^{13}C at 9.4 T. The data used to compute the spectra in (a) and (b) consisted of 1024 complex points in the ^1H dimension (t_2) and 128 complex points in the ^{13}C dimension (t_1). The spectrum in Figure 5(a) was computed by windowing with a 30° -shifted sine-bell, and zero filling to 2048 complex points prior to Fourier transformation in t_2 , followed by linear prediction using a filter order of 10 to extrapolate the data to 512 points in t_1 , windowing using a 45° -shifted sine-bell, zero filling to 1024 points and Fourier transformation. The data used to compute the spectrum in Figure 5(b) were obtained similarly to the data for (a) in t_2 , but exponential sampling using an effective decay time of 30 ms was used to collect 128 complex points, selected from a linear schedule of 512 points. Processing in t_2 was performed as before, but MaxEnt reconstruction was performed in t_1 , with values of 10 for def and 0.0554 for λ , and deconvolving a 20 Hz linewidth kernel. The data for Figure 5(c) consisted of 64 points exponentially sampled from a linear schedule of 256 points; the spectrum was computed as in (b). Comparison of (a) and (b) shows that nonlinear sampling in conjunction with MaxEnt reconstruction yields higher resolution than is achieved using conventional data acquisition and processing. In particular, the couplings between the leucine methyl protons and the γ proton are more clearly evident in (b). Comparison of (a) and (c) shows that exponential sampling can also be used to obtain resolution comparable to or better than conventional methods using less data. For long multidimensional experiments, even a reduction by a factor of 2 in experiment time can be significant.

Figure 5 Methyl region of the ^1H – ^{13}C HMQC spectra of $\alpha_1\text{B}$: (a) computed from 128-point (in t_1) conventionally acquired data using linear prediction, extrapolation, windowing, and Fourier transformation, (b) using MaxEnt reconstruction of 128-point exponentially sampled t_1 data, and (c) using MaxEnt reconstruction of 64-point exponentially sampled t_1 data

7.3 Deconvolution

MaxEnt reconstruction can also be used to deconvolve an arbitrary modulation. One application is to deconvolve J modulation. Figure 6 shows the same region of the HMQC spectrum of $\alpha_1\text{B}$ as Figure 5, but MaxEnt reconstruction has been used in the ^1H dimension to deconvolve the 7 Hz coupling. This method is equally applicable to spectra exhibiting antiphase modulation; however, it is only capable of deconvolving a single, fixed modulation frequency.

8 QUANTIFICATION

The nonlinearity of MaxEnt reconstruction is an inherent characteristic, and is responsible for the method's ability to achieve noise suppression without sacrificing resolution to the extent associated with linear filtering (such as the windowed DFT). This nonlinearity has important implications in situations where quantification of peak intensities or volumes is required, such as nuclear Overhauser effect measurements or difference spectroscopy. For difference spectroscopy, it may be sufficient to compute the difference using the time domain data and compute the MaxEnt reconstruction of the difference. This assures that the same

Figure 6 Methyl region of the ^1H - ^{13}C HMQC spectrum of $\alpha_1\text{B}$, with 7 Hz J modulation deconvolved in the ^1H dimension using MaxEnt reconstruction

nonlinearity applies to both experiments. When measuring nuclear Overhauser effects, or otherwise quantifying peak intensities, there are two possible approaches. One is to constrain tightly the reconstruction to match the data, which forces the reconstruction to be more nearly linear (although at the expense of noise suppression). Another is to inject synthetic signals of known relative intensity into the time domain data prior to reconstruction. A calibration curve can then be constructed by quantifying the intensities of the known signals.

The nonlinear nature of MaxEnt reconstruction also renders the S/N a poor estimate of sensitivity. Sensitivity estimates are perhaps best obtained by adding signals of known intensity to the data prior to reconstruction.

9 COMPUTATIONAL COST

The computational cost of MaxEnt reconstruction for one-dimensional spectra is typically 2 orders of magnitude greater than the cost of computing an FFT. For large, multidimensional reconstructions, the elapsed time is dominated by memory requirements, rather than the number of computations: the algorithm described above requires of the order of 16 times the size of the reconstructed spectrum for intermediate storage. While row-wise reconstruction can be used to ameliorate this requirement, fully multidimensional MaxEnt reconstructions remain the province of supercomputer-class machines with large amounts of high-speed random-access memory.

10 CONCLUDING REMARKS

Maximum entropy reconstruction is a powerful method for computing spectral estimates from time domain NMR data that avoids some of the limitations inherent in the discrete Fourier transform. It is more general than parametric methods, such as those based on linear prediction, that are restricted to Lorentzian signals, yet is capable of incorporating prior knowledge about the signal when it is available. The computational cost, while significantly greater than the FFT, is in a range that is practical on modern workstations, even for large data sets. Some of the power of the method stems from its nonlinearity, which dictates that the method must be used cautiously. Its ability to use nonlinearly sampled data

provides a powerful tool for improving the resolution and sensitivity of multidimensional experiments. Used prudently, MaxEnt reconstruction can extend the limits of sensitivity and resolution in NMR, simplify analysis, and enable the study of larger molecules and molecules at lower concentrations than is feasible using the DFT.

1 BACKGROUND AND PHENOMENOLOGY

In condensed matter, dipolar interactions among nuclear magnetic moments and their manipulation in multiple quantum (MQ) NMR experiments induce multiple spin correlations. The temporal and spatial development of these collective modes yield information about the structure and the dynamics of spin networks.¹⁻³ In this article, we examine the fundamental aspects of the growth of multiple spin/multiple quantum coherences in extended dipolar coupled spin networks driven by rf magnetic fields.

In MQ NMR, investigations of strongly dipolar coupled spin systems, such as rigid solids, the simplest relevant Hamiltonian needed to describe and understand experimental observations in a laboratory reference frame is given by

$$\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_d + \hat{\mathcal{H}}_{\text{rf}}(t) \quad (1)$$

The contributions to $\hat{\mathcal{H}}(t)$ in equation (1) include the interactions of the nuclear magnetic moments with a strong static magnetic field ($\hat{\mathcal{H}}_Z$), with other nuclear magnetic moments through dipolar interactions ($\hat{\mathcal{H}}_d$), and with time-dependent rf magnetic fields ($\hat{\mathcal{H}}_{\text{rf}}$). Furthermore, $[\hat{\mathcal{H}}_Z, \hat{\mathcal{H}}_d] = 0$, and $[\hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_d, \hat{\mathcal{H}}_{\text{rf}}] \neq 0$.

In order to simplify the description and make connection with experiments, the Hamiltonian of equation (1) is transformed to a frame rotating about the z axis of the laboratory frame at the nuclear spin precession frequency. In this new reference frame, $\hat{\mathcal{H}}_Z$ disappears. A further transformation to

another noninertial frame, the rf toggling frame which ‘follows’ the directions of the rf fields during a pulse sequence, produces an effective Hamiltonian $\hat{\mathcal{H}}_{\text{de}}(t)$. In this newest frame, $\hat{\mathcal{H}}_{\text{de}}(t)$ results from the modulation of $\hat{\mathcal{H}}_d$ by the time-dependent rf fields. The time average of $\hat{\mathcal{H}}_{\text{de}}(t)$ over the period of a cycle of a multiple pulse excitation sequence yields, under appropriate conditions, a time-independent average Hamiltonian $\hat{\mathcal{H}}_d$:

$$\hat{\mathcal{H}}_d = \sum_{j,k} D_{jk} f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k) \quad (2)$$

where D_{jk} is a dipolar coupling constant between spins j and k

$$D_{jk} = \frac{\gamma^2 \hbar^2 (3 \cos^2 \theta_{jk} - 1)}{2r_{jk}^3} \quad (3)$$

and $f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k)$ is a function of bilinear operators involving the components of the spin angular momentum operators $\hat{\mathbf{I}}$, of spins j and k .

Formally, the geometrical interpretations of these transformations correspond to unitary transformations on the state of the spin system (i.e. the density operator) and its dynamical variables (i.e. the spin angular momentum and Hamiltonian operators). The resulting interaction pictures associate different parts of the time dependence of the physical system [i.e. the spins in the sample evolving under the Hamiltonian in equation (1)] to the state of the system and to the dynamical variables. This procedure is generic to all NMR experiments involving the manipulation of spin Hamiltonians. By a judicious choice of a reference frame, different portions of the Hamiltonian can be selected to appear to dominate the spin dynamics; hence, the possibility to discriminate among the various contributions in a spin Hamiltonian. Such an approach underlies the success of NMR spectroscopy. It is noteworthy that these transformations, from one frame to another, inertial or noninertial, do not necessarily preserve the invariance and conservation principles of physics. For example, spin energies measured in the laboratory frame are different from those measured in the rotating frame, while the spin quantum numbers, $I = \frac{1}{2}$ for protons, remain identical. However, observations restricted within a reference frame will be consistent with known laws of physics.

In pulsed NMR experiments, the evolution of the spin system is detected in the rotating frame. The time development of the spin system under $\hat{\mathcal{H}}_d$ in the toggling frame is monitored directly, in multiple pulse line-narrowing sequences such as MREV-8, or indirectly, in MQ NMR, by stroboscopic observations when both the rotating and the toggling frames coincide.

A variety of rf multiple pulse sequences have been tailored to produce different average dipolar Hamiltonians $\hat{\mathcal{H}}_d$. In MQ NMR experiments,¹⁻³ $[\hat{\mathcal{H}}_Z, \hat{\mathcal{H}}_d] \neq 0$. The spin portions [see equation (2)] $f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k)$ of these nonsecular average dipolar Hamiltonians include, among the bilinear spin operators, terms like $\hat{I}_{jz}\hat{I}_{k\pm}$, and $\hat{I}_{j\pm}\hat{I}_{k\pm}$, where $\hat{I}_+$ and $\hat{I}_-$ correspond to the raising and lowering (or ladder) spin angular momentum operators, respectively. These operators in $\hat{\mathcal{H}}_d$ are responsible for the radiative coupling of Zeeman nuclear spin states with differing magnetic quantum numbers M_z by ± 1 and ± 2 .

Evolution under $\bar{H}_d$ for extended periods of time leads to nonstationary states with possibly larger differences in ΔM_z , as discussed in the next section. MQ NMR pulse excitation sequences for solids are specifically designed and optimized to generate multiple spin/multiple quantum coherences among the spins in a macroscopic sample.

The selection rules for the observation of transverse magnetization, or single spin/single quantum coherences, correspond to transitions with $\Delta M_z = \pm 1$. Thus, the creation and evolution of coherent superpositions of quantum states with $\Delta M_z \neq 1$ cannot be detected directly. Indirect piecewise mappings of multiple spin/multiple quantum coherences are accomplished through two-dimensional NMR methods as a function of the excitation and/or evolution times.¹⁻³ MQ NMR spectra obtained in this fashion reveal the presence of multiple spin/multiple quantum coherences with $\Delta M_z = n$, where n is the order of the coherences, in the sample during the excitation/evolution period (see Figure 1).

Figure 1 shows schematic MQ NMR spectra, obtained with time-resolved two-dimensional experiments, as a function of the excitation time. For a fixed excitation period, the spectral intensities decrease with increasing orders. With increasing excitation times, a redistribution of spectral intensities is observed to proceed or to 'flow' towards higher order coherences.

Understanding the behavior of the MQ NMR spectral intensity profiles of solids, as a function of order and excitation time, still poses an interesting challenge to NMR spectroscopists. Specifically, one would like to learn how the multiple spin dynamics depend on the lattice parameters and the space-filling properties of spin networks. Examples of the latter include spatial extent, morphologies, and effective dimensionalities of domain structures on mesoscopic length scales, i.e. in

the range 1 nm to 1 μ m, in condensed matter systems. More generally, the recognition of emergent properties, generic or universal behavior, amidst the complexities of this many-body problem with multiple scales, would deepen our understanding of the fundamental aspects of MQ NMR. These issues are addressed in the following sections, from the perspective of statistical mechanics.

2 ENSEMBLE CONSIDERATIONS

From a macroscopic point of view, in a MQ NMR experiment energy is pumped through rf magnetic fields produced by electronic devices into a solid sample residing in a strong static magnetic field. From a microscopic point of view, this injection of energy proceeds from individual nuclear magnetic moments, embedded in the lattice, to induce multiple spin correlations. Both the microscopic and macroscopic descriptions of the rf irradiation processes involve nonequilibrium driven systems: the macroscopic solid and the microscopic magnetic moments. As these experiments are performed in laboratories on a macroscopic scale, but interpreted microscopically, it is imperative to understand clearly how the macroscopic observables emerge from the numerous microscopic degrees of freedom.

A rigid solid is an aggregate of a large number of spatially fixed atoms. Various solids exist due to the nature of their constituents, which include atoms, ions, or molecules. In MQ NMR of rigid solids, ions and molecules lose their distinct identities on account of the through-space dipolar interactions among all magnetic moments. Hence, the spin network, consisting of the nuclear magnetic moments and their dipolar coupling constants, remains the only relevant and essential substratum onto which the microscopic degrees of freedom, the multiple spin coherences, evolve in MQ NMR experiments.

Solid samples used in MQ NMR investigations typically contain on the order of 10^{20} or more spins. The multiple spin correlations induced in spin networks by present-day MQ NMR methodologies involve coherences with up to possibly 10^2 spins. Consequently, the size difference between the sample and the multiple spin coherences suggests that the macroscopic observables, or responses, in MQ NMR experiments, arise from the random superposition of numerous multiple spin coherences. In other words, the sample could be viewed as an ensemble of loosely coupled subsystems.

Such a description of a macroscopic sample is certainly valid in liquid state NMR experiments, where under normal conditions, molecules behave as essentially independent subsystems. This outlook can also be extended to correlated molecular systems, as observed in critical fluctuations close to critical points.⁴ For example, close to a consolute temperature, the intermolecular interactions among molecules in a critical binary fluid contrive and lead to composition fluctuations over length and timescales that can be quite large compared with those associated with the molecules, but still much smaller than those of the macroscopic sample. However, care must be exercised with such an analogy, since in critical phenomena systems are at equilibrium, while MQ NMR has to do with nonequilibrium driven systems. Possibly a more appropriate comparison for MQ NMR would be with the growth kinetics and processes of domain structures observed during phase

Figure 1 Typical MQ NMR spectra of a rigid solid: spectral intensities $I(n, t)$ as a function of order n and excitation time t , with $t_1 < t_2 < t_3$

Figure 2 A macroscopic sample viewed as an ensemble of loosely coupled N -spin subsystems. Relevant length scales include: the lattice spacing a , the correlation length of a multiple spin coherence ξ , the extent of a subsystem l , and the sample size L , which satisfy $a < \xi < l \ll L$. Spins are denoted by $\bullet$. An 11-spin coherence is also shown, with the lines representing the dipolar coupling constants appearing in the product, which multiplies the corresponding product operator term of the density operator

separation of binary fluids.⁵ In this case, a similarity to critical phenomena exists; however, a richer behavior arises due to the nonequilibrium conditions and nonlinearity. In any event, the point at issue, that a macroscopic sample can be viewed, under certain conditions, as an ensemble of loosely coupled subsystems, where a subsystem can be one or several molecules, or even part of a spin network in a solid, would appear physically plausible.

Figure 2 shows a representation of a macroscopic sample as a statistical ensemble of N -spin subsystems. The number of spins N per subsystem is much smaller, by many orders of magnitude, than the total number of spins in the sample. The relevant length scales in this ensemble include the sample size L , the spatial extent of a subsystem l , the correlation length of the multiple spin coherences ξ , and the underlying lattice spacing a . This hierarchy of length scales satisfy the inequalities, $a < \xi < l \ll L$. Interaction energies between subsystems are assumed to be weak in comparison with interaction energies within the subsystems. This amounts to a neglect of surface effects for the MQ dynamics. Such approximation becomes more accurate in the limit when $\xi \ll l$. These effects are nevertheless necessary to achieve equilibrium or uniform spin temperature in the ensemble. The presence of the long-range dipolar interactions among the magnetic moments would appear to preclude or even invalidate this perspective of the sample as representing an ensemble of loosely coupled subsystems. However, as will be seen in Section 5, in time-resolved MQ NMR experiments, multiple spin coherences are ‘weighted’ by products of dipolar coupling constants. As it turns out, in spin networks, the distributions of dipolar coupling constants and their products are extremely wide. Since, at early excitation times, the MQ spin dynamics are dominated by the largest coupling constants and their products, the ensemble picture remains a good approximation for most experimental conditions. This approximation breaks down for mean field interpretations, e.g. MQ NMR experiments having infinite excitation periods.

Measurements performed over a short period of time on a macroscopic sample, made up of an ensemble of subsystems, correspond to averaging over the ensemble.⁷ When a physical property of a macroscopic system is equal to this property averaged over the subsystems, spatial ergodicity exists. In statistical mechanics, the Gibbs canonical ensemble is composed of identical systems from the macroscopic point

of view, i.e. they all have the same number of particles N , volume V , and temperature T . However, most systems are in different microscopic states. In the ensemble construction for a nonequilibrium driven macroscopic system, as described above, none of the subsystems need to be strictly identical. Instead, one assumes that statistical homogeneity is valid for the subsystems. On a subsystem scale, the statistical properties are stationary in space, i.e. a subsystem is statistically translationally invariant in space. Another feature of time-resolved MQ NMR measurements on such an ensemble, is the fact that, as the multiple spin coherences grow, so does their correlation length ξ . As the inequality $\xi < l$ must be satisfied for a consistent interpretation of the ensemble, this implies that the number of subsystems actually decreases as a function of time. This should be of no significant consequence, as long as $l \ll L$. Under present MQ NMR experimental conditions, these conditions are always satisfied, and the ensembles will consist of huge numbers of subsystems. Such ensembles yield asymptotic statistical states in experimental investigations.

Thus, a time-resolved MQ NMR measurement on a macroscopic solid is assumed to be equivalent to many independent measurements on the subsystems. Since the decomposition of the macroscopic sample into subsystems is not unique, the averaging process over the ensemble implied in a measurement is really a summation over the subsystems. As the spin dynamics are being probed on the scale of a subsystem, the response of the collective ensemble is taken to reflect the behavior of a typical subsystem. Underlying the spin dynamics are dipolar coupling constants and their products. Due to subtleties related to wide distributions and to averaging over products, the role of the couplings is more intricate than appears in the present discussion. For example, the distinction between average and typical behavior is very important in the MQ NMR of large spin networks.⁶ We shall return to these issues in Section 6.

3 QUANTUM MECHANICS OF AN N -SPIN SUBSYSTEM

The focus on the spin dynamics within a subsystem and the subsequent averaging over a large collection of subsystems, yields a more tractable avenue to the understanding of

MQ NMR of solids, rather than treating a single spin system consisting of 10^{20} or more spins. Nevertheless, on the timescale of MQ NMR experiments, the spin dynamics within a subsystem still retain some of complexities of the many-body problem.

In a subsystem consisting of N spins I , there are $(2I + 1)^N$ stationary states of $\hat{\mathcal{H}}_Z$. For $I = \frac{1}{2}$, these 2^N energy levels can be classified according to the magnetic quantum numbers M_z given by

$$M_z = \sum_i^N m_{iz} \quad (4)$$

where m_{iz} is the eigenvalue ($m_z = \pm \frac{1}{2}$) of the i th spin. These Zeeman states, in the magnetic field $\mathbf{B}_0$, have corresponding energies

$$E_z = -\gamma \hbar B_0 M_z \quad (5)$$

and degeneracies

$$\Omega = \frac{N!}{(\frac{1}{2}N + M_z)!(\frac{1}{2}N - M_z)!} \quad (6)$$

The Zeeman manifolds are further broadened by homonuclear dipolar perturbations $\hat{\mathcal{H}}_d$. The resulting energy level diagram can be characterized, in principle, by the combined eigenvalues and eigenfunctions of $\hat{\mathcal{H}}_Z$ and $\hat{\mathcal{H}}_d$. However, due to the presence of bilinear spin operators in $\hat{\mathcal{H}}_d$, the combined eigenfunctions are constructed from direct products of $\hat{\mathcal{H}}_Z$ eigenfunctions. As a consequence, the m_{iz} eigenvalues are not good quantum numbers. In addition, the presence of large N rapidly makes this approach analytically intractable.

Therefore, as a first approximation, only the energy level diagram due to $\hat{\mathcal{H}}_Z$ is considered. This is justifiable, since the Zeeman splittings are usually of the order of tens to hundreds of megahertz as compared with tens of kilohertz for dipolar splittings. Radiative coupling of pairs of Zeeman levels leads to

$$\binom{2^N}{2} = 2^N(2^N - 1)/2 \quad (7)$$

possible transitions. The distinction between $+n$ and $-n$ coherences results in $2^N(2^N - 1)$ transitions. These transitions, or coherences, are classified according to their orders n . The number of coherences of order $n \neq 0$, Z_n , where $|n| \leq N$, is obtained from the constrained sum over the products of degeneracies of coupled Zeeman manifolds,

$$Z_n = \sum_{M_i - M_j = n} \binom{N}{\frac{1}{2}N + M_i} \binom{N}{\frac{1}{2}N + M_j} = \binom{2N}{N - n} \quad (8)$$

The number of coherences within a Zeeman manifold or with $n = 0$, Z_0 , is given by

$$\begin{aligned} Z_0 &= \sum_{M_i = N/2+1}^{-N/2+1} \binom{N}{\frac{1}{2}N + M_i} \left[\binom{N}{\frac{1}{2}N + M_i} - 1 \right] \\ &= \binom{2N}{N} - 2^N \end{aligned} \quad (9)$$

Radiative coupling within a subsystem of N dipolar coupled spins $\frac{1}{2}$ can be rationalized, to a very good degree of approximation, on the basis of the possible $2^N(2^N - 1)$ transitions which connect the 2^N energy levels. The information content needed to describe this physical situation involves $2^N(2^N - 1)$ coherences and 2^N populations, or a total of 4^N parameters.

The 2^N eigenfunctions of $\hat{\mathcal{H}}_Z$, $|r\rangle$, for an N -spin- $\frac{1}{2}$ subsystem, constitute a complete basis set to characterize any spectroscopic experiments involving coherences and populations. As a consequence, any state $|\psi\rangle$ of a subsystem, can be expanded with the complete Zeeman basis set,

$$|\psi\rangle = \sum_{r=1}^{2^N} |r\rangle \langle r|\psi\rangle = \sum_{r=1}^{2^N} c_r |r\rangle \quad (10)$$

$$\langle r|\psi\rangle = c_r \quad (11)$$

Similarly, the observables or expectation values corresponding to any dynamical variables, such as the magnetization M_x , detected in a spectroscopic measurement on a subsystem, can be represented in this basis set with the corresponding operator $\hat{M}_x$ as,

$$\begin{aligned} \langle \psi|\hat{M}_x|\psi\rangle &= \sum_{r,s} \langle \psi|s\rangle \langle s|\hat{M}_x|r\rangle \langle r|\psi\rangle \\ &= \sum_{r,s} c_s^* c_r \langle s|\hat{M}_x|r\rangle \end{aligned} \quad (12)$$

where $c_r = \langle r|\psi\rangle$. The matrix elements $\langle s|\hat{M}_x|r\rangle$ are numbers related to the values of the dynamical variable M_x . The matrix elements, $c_s^* c_r$, are numbers describing the state $|\psi\rangle$ of the subsystem; there are 4^N such matrix elements. As a consequence, this matrix is isomorphic to, or has the same information content as, the description in terms of coherences and populations.^{8,9} The diagonal elements are proportional to the probabilities of occupation of the energy levels, and consequently to the populations. The off-diagonal elements correspond to correlations between the values of the coefficients c_r . For time-dependent problems, as in spectroscopic measurements, these off-diagonal elements are related to coherent superpositions of the stationary states, i.e. coherences or transitions, present in a spin subsystem.

Different states $|\psi\rangle$ yield different values for the same observable, as can be seen from equation (12). The products, $c_s^* c_r$, vary according to the states $|\psi\rangle$, while the matrix elements $\langle s|\hat{M}_x|r\rangle$ remain invariant. It proves convenient to describe the state of the subsystem, with a projection operator for a single state, $\hat{P}_\psi = |\psi\rangle\langle\psi|$, in the Zeeman basis set:

$$\langle r|\hat{P}_\psi|s\rangle = c_s^* c_r \quad (13)$$

With this projection operator, the expectation value of $\hat{M}_x$ in a subsystem becomes [see equation (12)]:

$$\begin{aligned} \langle \hat{M}_x \rangle &= \langle \psi|\hat{M}_x|\psi\rangle = \sum_{r,s} \langle r|\hat{P}_\psi|s\rangle \langle s|\hat{M}_x|r\rangle \\ &= \text{Tr}\{\hat{P}_\psi \hat{M}_x\} \end{aligned} \quad (14)$$

4 QUANTUM STATISTICAL MECHANICS OF AN ENSEMBLE OF N -SPIN SUBSYSTEMS

A measurement of M_x over an ensemble of subsystems is equivalent to averaging over $\langle \hat{M}_x \rangle$ in equation (14). As the state $|\psi\rangle$ or $c_{s,r}^*$ of each subsystem will generally be different, while the dynamical variable will be identical, the averaging gives

$$\overline{\langle \hat{M}_x \rangle} = \sum_{r,s} \overline{\langle r | \hat{P}_\psi | s \rangle \langle s | \hat{M}_x | r \rangle} = \text{Tr}\{\hat{\rho} \hat{M}_x\} \quad (15)$$

with $\hat{\rho}$, the density matrix of the ensemble,^{8,9} defined as

$$\langle r | \hat{\rho} | s \rangle = \sum_{\psi} p_{\psi} \langle r | \hat{P}_\psi | s \rangle = \overline{\langle r | \hat{P}_\psi | s \rangle} = \overline{c_{s,r}^* c_r} \quad (16)$$

where p_{ψ} is the statistical weight of $|\psi\rangle$ in the ensemble.

For NMR experiments, the density matrix is represented by a density operator, corresponding to the Boltzmann weight of the canonical ensemble with the appropriate Hamiltonian operator defined with respect to some convenient reference frame,

$$\hat{\rho} = Q^{-1} e^{-\hat{\mathcal{H}}/kT} \quad (17)$$

where Q is the ensemble partition function,

$$Q = \sum_{r=1}^{2^N} \langle r | e^{-\hat{\mathcal{H}}/kT} | r \rangle \quad (18)$$

The description of any spectroscopic experiment will involve the time dependence, due to evolution under some Hamiltonian $\hat{\mathcal{H}}$ of $\hat{\rho}$ to characterize the ensemble, or $\hat{P}$ to represent a subsystem. In the Schrödinger picture, the time dependence is assigned to the state of the system, specifically, to the coefficients $c_r(t)$ of equation (11).^{8,9} In MQ NMR experiments of solids, the relevant Hamiltonian corresponds to the time average of $\hat{\mathcal{H}}_d$ in the rf toggling frame, $\hat{\mathcal{H}}_d$ [see equation (2)], over a cycle of the rf excitation sequence. The equation of motion for $\hat{P}$ is obtained by inserting $|\psi\rangle$ into the time-dependent Schrödinger equation to yield^{8,9}

$$\frac{d\hat{P}}{dt} = \frac{i}{\hbar} [\hat{P}, \hat{\mathcal{H}}_d] \quad (19)$$

The averaging of equation (19) over the ensemble of subsystems with identical $\hat{\mathcal{H}}_d$ gives the equation of motion for $\hat{\rho}$:

$$\frac{d\hat{\rho}}{dt} = \frac{i}{\hbar} [\hat{\rho}, \hat{\mathcal{H}}_d] \quad (20)$$

Equation (20) is also known as the Liouville–von Neumann equation.

For a time independent average Hamiltonian, a formal solution to equation (20) is

$$\hat{\rho}(t) = \hat{U} \hat{\rho}(0) \hat{U}^{-1} \quad (21)$$

where the propagator $\hat{U}$ is defined as

$$\hat{U} = \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}}_d t\right) \quad (22)$$

The interpretation of equation (21) is of importance for understanding the development of multiple spin coherences in time resolved MQ NMR experiments. Insight in this many-body problem, as discussed in the next section, can be gained through a Taylor expansion of $\hat{\rho}(t)$ about $t = 0$:

$$\hat{\rho}(t) = \hat{\rho}(0) + \sum_{n=1}^{\infty} \frac{t^n}{n!} \frac{d^n}{dt^n} \hat{\rho}(t)|_{t=0} \quad (23)$$

From equations (21) and (22), one finds the derivatives of $\hat{\rho}(t)$, of which only the first two are given here:

$$\frac{d\hat{\rho}(t)}{dt} = \frac{i}{\hbar} [\hat{\rho}(0), \hat{\mathcal{H}}_d] \quad (24)$$

$$\frac{d^2 \hat{\rho}(t)}{dt^2} = -\frac{1}{\hbar} [[\hat{\rho}(0), \hat{\mathcal{H}}_d], \hat{\mathcal{H}}_d] \quad (25)$$

Finally, by substituting equations (24) and (25) and all the other derivatives into equation (23), one obtains:

$$\begin{aligned} \hat{\rho}(t) = & \hat{\rho}(0) + \frac{it}{\hbar} [\hat{\rho}(0), \hat{\mathcal{H}}_d] \\ & - \frac{t^2}{2\hbar^2} [[\hat{\rho}(0), \hat{\mathcal{H}}_d], \hat{\mathcal{H}}_d] + \dots \end{aligned} \quad (26)$$

5 DEVELOPMENT OF MULTIPLE SPIN/MULTIPLE QUANTUM COHERENCES IN DIPOLAR COUPLED SOLIDS

The power series in time for $\hat{\rho}(t)$ in equation (26) describes the evolution of the spin dynamics in MQ NMR experiments. With the initial conditions corresponding to the spin system at equilibrium in a strong Zeeman field at a high temperature, equation (17) implies

$$\hat{\rho}(0) \propto \hat{I}_z = \sum_i \hat{I}_{zi} \quad (27)$$

As pointed out in Section 3, since $|\hat{\mathcal{H}}_Z| \gg |\hat{\mathcal{H}}_d|$, it is appropriate to neglect the contributions of $\hat{\mathcal{H}}_d$ in the initial conditions. However, in the toggling reference frame, $\hat{\mathcal{H}}_d$ is crucial for determining the evolution of the spin dynamics. By inserting $\hat{\rho}(0)$ and the nonsecular average Hamiltonian $\hat{\mathcal{H}}_d$ suitable for a particular MQ NMR experiment into equation (26), it is possible to examine the qualitative features of the growth of multiple spin/multiple quantum coherences in a solid.

With $\rho(0)$ corresponding to single-spin interactions and $\hat{\mathcal{H}}_d$ to two-spin interactions, the ascending terms in the expansion of $\hat{\rho}(t)$ describe the sequential growth of multiple spin coherences due to the evolution under $\hat{\mathcal{H}}_d$. In the first-order terms t^1 , the commutators produces two-spin correlations of the form $\hat{I}_{i\alpha} \hat{I}_{j\beta}$, where the components α and β of the spin angular momentum operators are determined by the actual

details of $\hat{\mathcal{H}}_d$. The nested commutators in the second-order terms t^2 yield three-spin operators, $\hat{I}_{\alpha}\hat{I}_{\beta}\hat{I}_{\gamma}$. The hierarchy of nested commutators from the higher order terms t^n generate $(n - 1)$ -spin operators. By introducing ladder (raising and lowering) operators in these product operators, the order n of the corresponding MQCs becomes explicit; the sum of raising operators minus the sum of the lowering operators in a product operator gives the order of the coherence. Thus, to observe an n quantum coherence it is necessary to have, at the minimum, a contribution of order t^{n+1} , implying the presence of an n -spin/ n quantum operator in the expansion of $\hat{\rho}(t)$. Higher order terms can also produce n quantum coherences. The distinction between these different n quantum coherences comes from the number of spins participating in the correlations. Since multiple spin coherences contribute to equation (26) through the product of dipolar coupling constants (as discussed below and in Section 6), the lattice parameters r_{ij} and θ_{ij} will ultimately control and distinguish between the various n quantum coherences.

The interplay between the development of multiple spin coherences and the order of the resulting multiple quantum coherences depends on selection rules associated with the nature of $\hat{\mathcal{H}}_d$ and equation (26). With respect to the time development of the number of spins in multiple spin coherences, the bilinear spin operators of $\hat{\mathcal{H}}_d$ and the algebra of the nested commutators in equation (26) imply a cascade process in the growth of correlations. An n -spin coherence can only grow by sequentially incorporating one single spin at a time, one after another. The time development of multiple quantum coherences is constrained to pathways, in a K -spin/ n quantum space, which depend uniquely on the nature of $\hat{\mathcal{H}}_d$.^{2,10} The pulse excitation sequences for MQ NMR of solids produce generic classes of $\hat{\mathcal{H}}_d$ terms: 2-spin/0,2 quantum operators, 2-spin/1-quantum operators, and 2-spin/2 quantum operators. These excitation sequences achieve a redistribution of MQ NMR spectral intensities according to selections rules on ΔK and Δn . For example, with 2-spin/2 quantum operators in $\hat{\mathcal{H}}_d$, and an $\hat{I}_z$ initial condition, equation (26) and the selection rules $\Delta K = \pm 1$ and $\Delta n = \pm 2$, demonstrate that only even coherences develop; in addition, the evolution cannot generate 4-spin/4 quantum coherences. The redistribution of spectral intensities produced by the different $\hat{\mathcal{H}}_d$ terms is optimized according to the size or spatial distribution of the spins within a subsystem, e.g. for the detection of spin clusters, or extended spin networks.

One of the simplest models, the so-called statistical or Gaussian model,¹ used to interpret MQ NMR spectra of solids, consists of assuming that all the individual coherences possible in an N -spin subsystem have the same magnitudes with random phases, and that all have been excited at long excitation times in the sample or ensemble of subsystems. Time-reversal excitation produces transitions with identical phases within an order.¹¹ Hence, the assumption of a priori equal weight of the different coherences implies that the MQ NMR spectral intensities $I(n,t)$ are proportional to Z_n , [see equation (8)]. Stated differently, the distribution of coherences in the ensemble of subsystems is proportional to Z_n . For large N and small n , it is possible to transform Z_n in equation (8) with Stirling's approximation $y! \approx (2\pi y)^{\frac{1}{2}} y^y e^{-y}$ to give

$$Z_n \approx 4^N (\pi N)^{-\frac{1}{2}} e^{-n^2/N} \quad (28)$$

As a consequence, according to the statistical model, a MQ NMR spectral intensity profile as a function of order $I(n,t)$ should be Gaussian, as suggested by equation (28).

The time dependence of these profiles arises from the growth of the subsystem size $N(t)$. The variance $N(t)$ obtained from fitting $I(n,t)$ to a Gaussian function of n represents the effective number of dynamically coupled spins, in a typical subsystem, following an excitation period of duration t under $\hat{\mathcal{H}}_d$. In addition to spin counting with this variance, it has been suggested that the rate of change in $N(t)$ with time reflects on some of the space-filling properties, such as dimensionality effects, of spin networks.^{1,1,12-14} Qualitatively, three generic classes of behavior have been observed for $N(t)$. Saturation in $N(t)$ implies the presence of isolated clusters of spins. Unbounded growth curves are observed in extended spin networks. Saturation behavior seen at early excitation times, followed by unbounded growth, indicates the occurrence of coupled clusters of spins.

The simplicity of the statistical model accounts for its widespread use in the MQ NMR literature of solids.^{2,3} However, some questions have been raised concerning the validity of the assumption of the a priori equal weight of all coherences.^{2,6} In addition, the convenience of the Gaussian model with the use of simple fitting procedures to analyze MQ NMR spectral intensity profiles is not successful with extended spin networks.¹⁵ To appreciate the nature of these problems, and to understand the development of multiple spin/multiple quantum coherences in solids beyond the level of the statistical model, it is necessary to consider further fundamental aspects of the spin dynamics in MQ NMR.

As discussed in previous sections, the interpretation of MQ NMR experiments of solids relies on the spin dynamics within a subsystem, followed by averaging over an ensemble of subsystems. The density operator $\hat{\rho}$ in equation (17) and its equation of motion [equation (26)] reflect this two-fold averaging: a quantum mechanical averaging or the determination of expectation values in a subsystem [equation (14)], and a statistical averaging over the expectation values due to the distribution of subsystem states in the ensemble [equations (15) and (16)].

It is possible to construct a statistical ensemble of diagrams or graphs, including evolution, which is completely isomorphic with the density operator formalism used to describe MQ NMR.² This approach provides complementary physical insights into MQ NMR spin dynamics, averaging, and measurements. The diagrams include vertices corresponding to spins, and edges or links to delineate dipolar coupling constants between spins. The weight of an edge is proportional to the absolute value of the dipolar coupling constant. The state of a spin is represented by a color. For a spin $\frac{1}{2}$ there are three colors, $\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$; generalization to higher spins is possible.

The decomposition of the density operator proceeds by examining an N -spin subsystem, under rigid lattice conditions and without any symmetry elements. In such an N -spin subsystem, the number of distinct subsets n_i each containing i spins is given by the binomial coefficient:

$$n_i = \binom{N}{i} \quad (29)$$

For example, the number of pairs of spins or dipolar coupling constants in a single subsystem is n_2 . The subsets can range in size from $i = 1$ to N . The sum over all possible subsets is:

$$n_T = \sum_{i=1}^N n_i = \sum_{i=1}^N \binom{N}{i} = 2^N - 1 \quad (30)$$

In equation (30), n_T is the sum of all possible spin correlations in the spin subsystem. By including the states of the spins or colors within the spin correlations, one obtains

$$n_T^c = \sum_{i=1}^N n_i 3^i = \sum_{i=1}^N \binom{N}{i} 3^i = 4^N - 1 \quad (31)$$

where n_T^c is the total number of distinct colored subsets, and is equal to the number of elements (coherences and populations) of the normalized density operator in an N -spin- $\frac{1}{2}$ subsystem.

The growth of multiple spin/multiple quantum coherences is described by equation (26). From the interpretation of this equation, the coherences were seen to grow sequentially by adding one spin after another with increasing time. It is clear that this description is valid for the density operator, either in the product operator formalism or in the ensemble of colored spin correlations described above.

However, there is an essential feature related to the growth processes and the averaging over the subsystems, which becomes more obvious with the diagrams. Consider a generic term of $(n + 1)$ th order in the Taylor expansion of equation (19) for the time dependence of the projection operator $\hat{P}_\psi$. The resulting equation is analogous to equation (26) with $\hat{P}_\psi$ replacing $\hat{\rho}$. The product of spin operators will include n -spin operators corresponding to different spins in the subsystem. As $\hat{\mathcal{H}}_d$ is present in the nested commutators, there will also be products of $(n - 1)$ dipolar coupling constants which multiply the n -spin product operators. For example, a 3-spin coherence involving spins i, j , and k , will have a corresponding product operator of the form $\hat{I}_{i\alpha}\hat{I}_{j\beta}\hat{I}_{k\gamma}$, multiplied by a product of dipolar coupling constants $D_{ij}D_{jk}$. Hence, in general, the contributions or weights of n -spin coherences in the equation of motion are determined by products of $(n - 1)$ dipolar coupling constants. A diagram, consisting of n vertices connected with $(n - 1)$ edges is called a tree; no loops are permitted in such a graph. The number of ways to connect n vertices, with $(n - 1)$ edges chosen among $\binom{n}{2}$ distinct edges, corresponds to the number of distinct trees given by

$$n^{n-2} \quad (32)$$

Equation (32) also gives the number of products of n dipolar coupling constants for a particular n -spin coherence. In an N -spin subsystem, the total number of products of n dipolar coupling constants for n -spin coherences is

$$\binom{N}{n} n^{n-2} \quad (33)$$

The averaging over an ensemble of subsystems, in order to obtain $\hat{\rho}$, as discussed in Section 4 and in NMR texts,^{8,9} proceeds by assuming that the Hamiltonians are identical for all

subsystems [see equations (19) and (20)]. This is certainly true for a hypothetical representative ensemble, or approximately true for a sample viewed as an ensemble of loosely coupled subsystems, as presented in Section 2. However, when the averaging is done over a nonequilibrium ensemble for a finite sample, care must be taken to distinguish between the sum in the Hamiltonian [see equations (2), (19) and (20)] and the realizations of multiple spin correlations (with corresponding product operators) present in the ensemble. As an example, consider a 25-spin subsystem. In this subsystem, there is only a single MQ coherence of order 25 represented by a product operator consisting of 25 raising operators. According to equation (26), the 25-spin/25 quantum coherence is weighted by a product of 24 dipolar coupling constants. Among these spins, there are $\binom{25}{2} = 300$ distinct dipolar coupling constants. The number of distinct products of 24 dipolar coupling constants corresponds to the number of trees, in this case $25^{23} \approx 10^{32}$ realizations. It should be clear that a macroscopic sample consisting of 10^{20} spins will not have enough 25-spin subsystems to represent all trees or possible realizations of the 25-MQ coherence. An MQ NMR measurement on a macroscopic sample, consisting of an ensemble of subsystems, is really an average over the subsystems [see equation (16)]. The average over multiple spin coherences is really performed over the distribution of corresponding trees present in the ensemble, i.e. over products of dipolar coupling constants. To appreciate the intricacies of such a measurement or averaging procedure, we now examine the distributions of dipolar coupling constants and their products in spin networks.

6 STATISTICAL PROPERTIES OF DISTRIBUTIONS OF DIPOLAR COUPLING CONSTANTS AND THEIR PRODUCTS IN LARGE SPIN NETWORKS

Consideration of equation (26) demonstrated that different multiple spin coherences contribute to the evolution of ρ according to the values of the products of dipolar coupling constants. Thus, for a finite excitation time, coherences cannot be treated equally, as is assumed in the Gaussian statistical model.¹ Only in the limit of an infinite excitation time will all the coherences contribute equally to the spin dynamics.⁶ The recognition that in spin networks the distributions of dipolar coupling constants and their products are characterized by asymmetry associated with extreme widths is important for understanding MQ NMR spin dynamics.⁶ Difficulties encountered with the interpretation of equation (26), due to the presence of multiple length- and timescales, actually arise from these broad and peculiar distributions.

In three-dimensional solids, lattice sums of dipolar coupling constants can be replaced by a continuum approximation involving integrals such as

$$\sum_{i,j} D_{ij} \propto \int_r (1/r^3) r^2 dr \propto \ln r \quad (34)$$

For an infinite sample, the lattice sum diverges, while for finite spin networks the sum is conditionally convergent, i.e. it depends on the sample shape. Some approaches, such as the Ewald summation and the Lorentz cavity method, have

been devised to study these distributions in samples of general shapes.

In one-dimensional solids, the lattice sums can be performed analytically. Consider an infinite crystalline one-dimensional chain of spins with lattice parameter r oriented perpendicular to the Zeeman field. The average dipolar coupling constant per spin $\langle D \rangle_s$ is

$$\langle D \rangle_s = 2 \sum_{k=1}^{\infty} \frac{1}{2} \gamma^2 \hbar^2 (kr)^{-3} \approx 1.20 \gamma^2 \hbar^2 / r^3 \quad (35)$$

In this case, 83% of the average is determined by the value of two nearest neighbor couplings out of an infinity of couplings!

Figure 3 shows a schematic distribution of the absolute values of dipolar coupling constants and their logarithms for a large spin subsystem. One should note that the distribution in Figure 3(a) is really a caricature, since in large networks the width essentially cannot be observed on linear scales.⁶ Several statistical features are illustrated by Figure 3. The average $\langle |D| \rangle$ is determined by the coupling constants in the tail of the distribution, while the most probable value $|D|_{MPV}$ is sensitive to the small and numerous long-range couplings. The transformation of the distribution on a logarithmic scale demonstrates the huge dynamic range of the distribution. For example in a two-dimensional square lattice of $10^2 \times 10^2$ spins, the distribution of coupling constants covers over 10 orders of magnitude. Differences between $\langle \ln |D| \rangle$ and $\ln \langle |D| \rangle$ are important to reconcile with measurements on an ensemble. The value of $\langle |D| \rangle$ is sensitive to the largest coupling constants, while $\langle \ln |D| \rangle$ is more sensitive to the details of the overall distribution. Such distinctions are significant in the physics of

Figure 3 (a) Schematic distribution of the absolute values of dipolar coupling constants in an N -spin subsystem. (b) Schematic distribution of the logarithm of the absolute values of dipolar coupling constants in the same subsystem. Note the difference between $\langle \ln |D_{ij}| \rangle$ and $\ln \langle |D_{ij}| \rangle$. The analogous distributions, involving products of dipolar coupling constants, show similar behavior, but with wider distributions

disordered systems.^{16,17} Products of dipolar coupling constants show similar features; however, the distributions are even wider.⁶

Probably the most interesting feature of these distributions arises from the scaling behavior of the statistical properties as a function of N , the number of spins. The relative fluctuations RF,

$$RF = \frac{(\langle |D|^2 \rangle - \langle |D| \rangle^2)^{1/2}}{\langle |D| \rangle} \quad (36)$$

measure the relative spread about the mean. In the limit of large spin networks,

$$RF \propto N^{+1/2} \quad (37)$$

This result implies that the distributions become wider as N increases, i.e. there is no self-averaging. The ratio of the most probable value to the first moment can be shown to scale as $N^{+3/2}$. The product of dipolar coupling constants shows a similar behavior with the same scaling exponents.⁶ Such behavior is highly counterintuitive, since in random additive processes, within the central limit theorem, the relative fluctuations scale as $N^{-1/2}$, and the most probable value coincides with the first moment in the thermodynamic limit.

Some implications of these results for the growth of multiple spin coherences/multiple quantum coherences are beginning to emerge.^{2,18} For example, anisotropy effects in the growth process should be determined by the products of the angular contributions of dipolar coupling constants. In a measurement on an ensemble of subsystems, the realizations of multiple spin coherences which are detected should be those with the largest products of dipolar coupling constants. However, these products are the least numerous but still dominate the dynamics due to their large weights. This last result would suggest that a single subsystem, where a multiple spin coherence with the largest possible product has been excited, could eventually dominate a macroscopic measurement. The statistical properties of the distributions of dipolar coupling constants and their products should also be relevant for other aspects of strongly dipolar coupled spin systems; examples include problems associated with FIDs¹⁹ and the lineshapes,²⁰ spin diffusion,²¹ and spin temperature.²²

7 DYNAMICAL SCALE INVARIANCE IN THE GROWTH OF MULTIPLE SPIN CORRELATIONS IN DIPOLAR COUPLED SOLIDS

Dilation or scaling symmetry, observed under certain conditions in some physical systems, is a generalization of the concept of similarity among geometrical objects. In geometry, the properties of two circles with different radii are similar to one another by simple transformations of scales. In physical sciences, the practical aspects of scaling involve the determination of the relevant scaled variables to describe a phenomenon, such that all data acquired under a range of conditions collapse onto some single universal plot. Thus, scaling reveals an invariance or a kind of unification among the relevant scaled variables, which was not obvious

in the original unscaled variables. Understanding the physical reasons underlying scaling symmetry usually leads to deeper insights into the phenomenon.

Some scaling arguments have been applied to various aspects of the growth of multiple spin/multiple quantum coherences in solids.^{1,2,15,23} In the context of the Gaussian statistical model, studies have focused on the behavior of the variance $N(t)$ in dilution effects¹ and power law growth² in spin networks, and dimensional analysis of growth curves.²³ A more elaborate scaling analysis of MQ NMR spectral intensity profiles, as a function of order and excitation time, demonstrated non-Gaussian behavior in extended spin networks.¹⁵ These studies also provided additional support for the case of exponentially decaying intensity profiles. Behind these approaches lies the belief that the physics of the growth processes should be invariant or scale free, for some range of length- and timescales.

Baum et al.¹ have studied the effects of dilution of spin networks with MQ NMR. With increasing dilution, the growth curves $N(t)$ were shifted to longer excitation times. When the excitation time was multiplied by a scaling factor, all growth curves for the diluted systems could be collapsed onto the data of the undiluted or 'pure' spin network. In this case, the scaling symmetry demonstrates the invariance of the physics of the growth processes in the pure and diluted spin networks. A simple dilution in time relates these different systems. The scaling factor was observed to be a function of dilution; no serious attempts were made to understand this phenomenology.

Lacelle² has studied the growth curves $N(t)$ of a large variety of solid samples. All the data were seen to follow power law behavior,

$$N(t) \propto t^\alpha \quad (38)$$

where α is a growth exponent characteristic of the samples and the growth mechanism. The presence of power law growth indicates a scale invariant process, such that the functional

$$N(\lambda t) = \lambda^\alpha N(t) \quad (39)$$

exists for any values of the scaling factor λ . The solution of equation (39), i.e. equation (38), is obtained by setting $\lambda = 1/t$ in equation (39). In order to determine the physics behind the growth exponents, several models were considered. For example, in diffusive growth, the length scale ξ of the multiple spin correlations should follow

$$\xi \propto t^{1/2} \quad (40)$$

The space-filling properties of a homogeneously embedded solid in D dimensions imply that

$$N \propto \xi^D \quad (41)$$

Equations (40) and (41) yield

$$N \propto t^{D/2} \quad (42)$$

from which the growth exponent $\alpha = D/2$ is deduced for a diffusive growth mechanism. None of the models developed could account successfully for all the observed growth

exponents. However, a classification of the spin networks could be achieved with the long time behavior of the growth rates

$$\frac{dN}{dt} \propto t^{\alpha-1} \quad (43)$$

When $\alpha < 1$, the growth rates converge to zero at long excitation times, implying the presence of clusters of spins. When $\alpha > 1$, a divergence in the growth rates should occur, which indicates the presence of an extended network. The case of $\alpha = 1$ corresponds to the threshold between these regimes. In a sense, α serves as a localization/delocalization criterion for multiple spin coherences.

Scruggs and Gleason²³ have examined the growth curves of different simple crystalline materials. By assuming that the growth processes were only determined by a relevant time-independent scale, the inverse of the square root of the second moment of the dipolar linewidths, the different growth curves collapsed onto a single universal curve for early excitation times. Their assumption for this empirical scaling is implicitly equivalent to assuming that the growth processes are dominated by nearest neighbor couplings, since Van Vleck's second moment is also dominated by such couplings.

One could argue about the quality and the quantitative aspects of the fitting procedures with the Gaussian approximation in these studies.^{1,2,23} However, the value of such studies really lies in the efforts made to explore the possible facets of scaling in the growth processes of multiple spin/multiple quantum coherences. To ascertain any quantitative aspects of scaling, for example, growth exponents, under these circumstances it is clear that many more experiments involving high quality data will be required.

Lacelle et al.¹⁵ have developed some scaling arguments in order to test the validity of the Gaussian statistical model. In particular, they strived to observe the scaling of MQ NMR spectra, as a function of order and excitation times, in extended spin networks. The Gaussian dependence suggested for the spectral intensity profiles $I(n,t)$ in equation (28) is actually a generalized homogeneous equation. With the time dependence of the variance $N(t)$ corresponding to a random walk model in product operator space,^{1,10} the expected scaling, $I(n,t)/t^{-1/2}$ versus $n/t^{1/2}$, should have collapsed all MQ NMR spectra for a sample onto a single universal spectrum. The lack of scaling clearly demonstrated non-Gaussian behavior. Instead, consideration of the multiplicative nature of the coupling constants associated with product operators in equation (26) led to a heuristic argument predicting exponential decaying intensity profiles. The ensuing scaling analysis collapsed MQ NMR spectra, obtained at different excitation times, onto a single universal spectrum, thereby demonstrating dynamical scale invariance in the growth process of multiple spin/multiple quantum coherences. Such an approach reveals some aspects of the complexities, richness, and subtleness of multiple spin dynamics in MQ NMR of solids.

1 INTRODUCTION

Multiple quantum (MQ) NMR can provide unique insight into the distribution and motion of nuclei in solids. In this article, we consider multiple quantum coherences associated with homonuclear dipolar coupling among spin- $\frac{1}{2}$ nuclei in solids. Therefore, we consider nuclei with high natural isotopic abundance and a high gyromagnetic ratio. ^1H MQ NMR has been applied to study organic solids,^{1–3} amorphous semiconductors,^{4–7} and adsorbates on catalysts^{8–14} and chromatography columns.¹⁵ In addition, ^{19}F MQ NMR has been used to study bulk salts,¹⁶ photosensitive salt/polymer mixtures,^{17–19} and bulk polymers.²⁰ MQ NMR of ^{31}P in solids has also been demonstrated.²¹ Several review articles and textbook chapters on MQ NMR experiments and their applications are available.^{21–29}

The rate of MQ coherence development depends on the strength and time dependence of each pairwise homonuclear dipolar coupling as well as the number of such pairs. For a network of N equivalent nuclei, the second moment M_2 of the distribution of all the pairwise homonuclear dipole couplings can be related to the geometry of the spin distribution through the van Vleck equation:³⁰

$$M_2 = \frac{3}{4} \gamma^4 \hbar^2 \frac{I(I+1)}{2} \sum_{i < j}^{N-1} \frac{(1 - 3 \cos^2 \theta_{ij})^2}{r_{ij}^6} \quad (1)$$

Thus, many combinations of internuclear distances r_{ij} and the total number of pairs in the summation $N - 1$ can give rise to identical M_2 . Using MQ NMR, the number and distribution of dipolar couplings can be investigated independently, thus allowing the distribution of nuclei in a solid to be explored.

Observation of MQ coherence development in solids is accomplished interferometrically via a two-dimensional NMR technique.^{1,29} By incrementing the MQ preparation time τ , the presence of finite clusters of nuclei can be distinguished from nuclear distributions which are homogeneous on the 1–2 nm length scale of this experiment.^{2,3} Coherences arising from a

cluster of nuclei will saturate with increasing MQ excitation time, because no additional nuclei are available for correlation in the surrounding region. In contrast, the number of nuclei coupled together in a large homogeneous dipole network will increase monotonically with time until relaxation occurs.

Furthermore, a simple scaling exists for the growth of MQ coherences among many bulk materials.^{16,31} This behavior allows homogeneous three-dimensional distributions of nuclei to be differentiated from one- and two-dimensional distributions.^{31–33} Identification of two-dimensional distributions is particularly valuable for determining whether a given nuclear species, such as ^1H , ^{19}F , or ^{31}P , is segregated at a surface,^{31,34} such as a grain boundary in a polycrystalline material. A model which expands the density matrices in terms of average product operators allows these differences to be evaluated numerically.³¹

More complex distributions of nuclei can also be analyzed using MQ NMR. For example, both isolated salt molecules and large aggregates of salt have been observed simultaneously within polymeric matrices.^{17–19} Finally, MQ NMR and its relaxation may serve as a valuable probe of molecular reorientation in solids which modulate the dipolar coupling network at frequencies in the kilohertz range.^{20,35,36}

2 MQ COHERENCE INTENSITIES

Analysis of MQ intensities is the underlying principle for using MQ NMR as a ‘spin-counting’ technique, allowing the number of dipole coupled nuclei in a isolated cluster to be determined.³ Although only two possible states, α and β , exist for an individual spin- $\frac{1}{2}$ nucleus, when N of these nuclei are dipole coupled there are 2^N possible product states. Thus, a $2^N \times 2^N$ density matrix is required to represent fully the time development of MQ coherence intensity among N dipolar coupled spin- $\frac{1}{2}$ nuclei. A schematic representation of ρ for $N = 3$ is shown in Figure 1, where the indices of the matrix are the eight possible product states. Diagonal elements can be used to calculate the populations of the product states, while the off-diagonal elements indicate the MQ coherences between two different states.

The MQ coherence order, n , is equal to the difference in m_z between the two states. Since the z component of angular momentum m_z of an individual spin state is $\pm\frac{1}{2}$, m_z for the product states ranges from $-N/2$ to $+N/2$. Thus, MQ orders can be positive, negative, or zero, provided that $|n| \leq N$. This limitation provides a very elegant way of determining the number of dipole coupled spins in a spatially isolated cluster. However, there is only one way to achieve such an $n = N$ coherence, making it statistically difficult to observe intensity in highest MQ order for large N . Fortunately, the number of density matrix elements Z_n for lower order coherences ($|n| < N$) also depends on the number of coupled nuclei:

$$Z_n = \sum_{i < j} \delta_{[(m_{zi} - m_{zj}), n]} = \binom{2N}{N - |n|} \quad (2)$$

In this equation, Z_0 includes both off-diagonal elements with $n = 0$, representing true zero quantum coherence (0Q), and diagonal elements representing self-correlation among the

Figure 1 Schematic representation of ρ for $N = 3$. The 2^3 product states are sorted by m_z so that elements corresponding to even MQ coherences ($n = 0$, black; $|n| = 2$, striped) appear in the upper left and lower right quadrants. The remaining elements correspond to odd MQ orders ($|n| = 1$, white; $|n| = 3$, grey)

states, as no difference is resolved between these two types of element by most MQ experiments.

Each element in Figure 1 is shaded according to the absolute value of its corresponding MQ order. Note that the first $4^{N/2}$ indices in Figure 1 represent the states with $m_z = (N - k)$, where k is an integer. Thus, elements corresponding to even order MQ coherences will appear only in the upper left and lower right quadrants of the density matrix. The remainder of the elements in the upper right and lower left quadrants correspond to odd order MQ coherences. If only even order MQ coherences are excited, this density matrix will be block diagonal with only $4^{N/2} = 32$ possible nonzero elements. For $N = 3$, the number of elements contributing to the even orders will be $Z_0 = 20$ and $(Z_2 + Z_{-2}) = 12$.

At equilibrium, the density matrix is proportional to I_z . Thus, only the diagonal elements are nonzero. As MQ excitation begins, intensity develops in density matrix elements of low MQ order. Longer excitation times are required for growth of high-order MQ coherences. The n quantum intensity at any time τ after MQ excitation is begun $I_n(\tau)$, contains contributions from all Z_n density matrix elements comprising that order:³⁷

$$I_n(\tau) = \sum_{i < j} \delta_{[(m_{zi} - m_{zj}), n]} |\rho_{ij}(\tau)|^2 \quad (3)$$

Thus, calculation of MQ dynamics requires following the time evolution of the density matrix under the influence of the Hamiltonian corresponding to the MQ excitation sequence during the experiment.

The Liouville von Neumann equation of motion can be used to calculate $\hat{\rho}(\tau)$ explicitly:

$$\frac{d\hat{\rho}(\tau)}{d\tau} = i[\hat{\rho}(\tau), \hat{\mathcal{H}}] \quad (4)$$

where $\hat{\mathcal{H}}$ is the Hamiltonian applied to the system for a duration τ in order to develop MQ coherences. If average

Hamiltonian theory can be applied, the solution of equation (4) is

$$\hat{\rho}(\tau) = \exp(-i\hat{\mathcal{H}}\tau)\rho(0)\exp(i\hat{\mathcal{H}}\tau) \quad (5)$$

For small numbers of spins ($N \leq 9$), the development of $I_n(\tau)$ has been calculated explicitly using equations (3) and (5).^{32, 37, 38}

However, tracking the time development of the 4^N density matrix elements is a large task for any significant number of coupled spins. For $N = 95$, the number of density matrix elements exceeds the number of hydrogen atoms in the Earth's sun! Thus for a large N , statistical limit behavior is often assumed, in which all MQ coherences have equal probability, allowing the magnitude of all density matrix elements to become equal at long excitation times.

The assumption of a statistical limit³⁷ greatly simplifies the analysis of MQ coherence intensities since the intensity of an n quantum coherence depends only on the number of elements of that order Z_n :

$$I_n = \frac{C Z_n}{4^N} \quad (6a)$$

The inverse of the constant C represents the fraction of density matrix elements where nonzero intensity could be excited. This fraction depends upon the selectivity of the Hamiltonian applied to the system. When nonselective excitation is used, all MQ orders are excited and $C = 1$. However, selective MQ excitation is often used. For instance, if only even MQ orders are excited, $C = 2$. Since equation (2) shows that Z_n is a function of n and N only, the distribution of $I_n(\tau)$ allows N to be determined. When $N \geq 6$, the right-hand side of equation (6a) can be approximated by a Gaussian distribution:

$$I_n \simeq \frac{C}{\sqrt{N\pi}} \exp(-n^2/N) \quad (6b)$$

Equations (6a) and (6b) are valid for all positive, negative and zero integer values of n , and are normalized such that

$$\sum_{n=-\infty}^{\infty} I_n = 1 \quad (7)$$

In addition, note that the MQ intensity distribution is symmetric, $I_n = I_{-n}$, and that I_0 contains both populations and true 0Q coherences. Furthermore, higher order coherences are statistically more difficult to achieve than lower order coherences. As will be shown below, I_0 tends to deviate more from the predicted values than the positive orders; only the latter are generally utilized to determine N . Statistical limit behavior is often a poor assumption for very small groups of spins, due to presence of symmetry forbidden transitions.

3 MQ EXCITATION BY $\hat{\mathcal{H}}_{yx}$

One of the most desirable Hamiltonians for exciting MQ coherences in solids is $\hat{\mathcal{H}}_{yx}$:

$$\hat{\mathcal{H}}_{yx} = -\frac{1}{2} \sum_{i < j} R_{ij} (\hat{I}_{i+} \hat{I}_{j+} + \hat{I}_{i-} \hat{I}_{j-}) \quad (8)$$

Other Hamiltonians such as $\hat{\mathcal{H}}_{zx}$ have been used for exciting MQ coherences. However, higher orders develop more quickly under $\hat{\mathcal{H}}_{yx}$,³⁸ maximizing the number of spins that can be correlated before relaxation effects become significant.

The bilinear raising and lowering operators $\hat{I}_{+i}\hat{I}_{+j}$, and $\hat{I}_{-i}\hat{I}_{-j}$ allow only even-order MQ coherence intensity to evolve when $\hat{\mathcal{H}}_{yx}$ is utilized in conjunction with an equilibrium initial density matrix $\rho(0)$ that is proportional to $\hat{I}_z$. When only half of all possible orders are excited, the intensity of each is twice that of a nonselective experiment [equation (6)]. The increased intensity is particularly important for detecting high-order coherences, which are statistically less likely than lower order coherences. Odd order and nonselective excitation using $\hat{\mathcal{H}}_{yx}$ results when prepulses create an initial density matrix proportional to the single quantum operator $\hat{I}_x$ or it can be made nonselective if $\rho(0)$ is a mixture of $\hat{I}_z$ and $\hat{I}_x$, respectively.⁴⁰

For spin counting applications it is important to note that the selection rules for $\hat{\mathcal{H}}_{yx}$ from an initial density matrix proportional to $\hat{I}_z$ result in the inability to create $n = N$ quantum coherence. Obviously, N quantum coherence cannot be developed when N is odd. More surprisingly, N quantum coherence cannot be achieved among $N = 4k$ dipole coupled spins, where k is a positive integer.⁴⁰ Thus, four quantum coherence cannot develop among an isolated cluster of four coupled nuclei. While these limitations appear problematic, the ability to achieve N quantum coherence via other MQ propagators can be even more restrictive. For instance, under $\hat{\mathcal{H}}_{zx}$ the N quantum order can never be achieved when starting from the equilibrium density matrix. The restrictions on creating N quantum coherence are only significant for size determination among very small clusters of nuclei. In larger dipole coupled networks, the signal-to-noise ratio of the highest order MQ coherence is generally below the detection limit, rendering the ability to achieve this coherence insignificant.

To carry out the MQ experiment in the laboratory, the phase ϕ of $\hat{\mathcal{H}}_{yx}$ is generally varied.^{1,2} One or more repetitions of the eight-pulse cycle shown below have been used to create $\hat{\mathcal{H}}_{yx}(\phi)$:

$$\begin{aligned} &(\Delta/2) - 90^\circ_\phi - (\Delta') - 90^\circ_\phi - (\Delta) - 90^\circ_\phi - (\Delta') - 90^\circ_\phi - \\ &(\Delta) - 90^\circ_{\phi+180^\circ} - (\Delta') - 90^\circ_{\phi+180^\circ} - (\Delta) - 90^\circ_{\phi+180^\circ} - \\ &(\Delta') - 90^\circ_{\phi+180^\circ} - (\Delta/2) \end{aligned}$$

where $\phi = 0^\circ$ corresponds to an x pulse. The relationships between the delays is $\Delta' = 2\Delta + t_p$, where t_p is the pulse length. The average Hamiltonian, $\hat{\mathcal{H}}_{yx}(\phi)$ is then

$$\begin{aligned} \hat{\mathcal{H}}_{yx}(\phi) = & -\frac{1}{2} \sum_{i < j} R_{ij} [\hat{I}_{i+}\hat{I}_{j+} \exp(2i\phi) \\ & + \hat{I}_{i-}\hat{I}_{j-} \exp(-2i\phi)] \end{aligned} \quad (9)$$

Considering $0^\circ \leq \phi < 360^\circ$, $\hat{\mathcal{H}}_{yx}(\phi) = \hat{\mathcal{H}}_{yx}$ at $\phi = 0^\circ$ or 180° and $\hat{\mathcal{H}}_{yx}(\phi) = -\hat{\mathcal{H}}_{yx}$ at $\phi = 90^\circ$ or 270° . During the

mixing period, the value of ϕ is fixed at 90° , corresponding to $-\hat{\mathcal{H}}_{yx}$.

In the presence of heteronuclear couplings, the $\hat{\mathcal{H}}_{yx}$ sequence can be used to examine the distribution of I spins without irradiation of the S spin frequency or reduction of the I - S couplings by isotopic exchange.¹⁶ This is particularly important when both ^{19}F and ^1H are present in the sample of interest.

As in any multiple pulse NMR experiment, deviations from perfect delta pulses, finite pulse cycle times with respect to the inverse frequencies of the interactions in the sample, and off-resonance effects can lead to undesirable effects.⁴² The sensitivity to chemical shift offset has recently been exploited to measure the correlation length of the chemical shift shielding tensor in polycrystalline solids.⁴³ This increased sensitivity of higher order coherences to magnetic field gradients has also been exploited to enhance the spatial resolution of NMR imaging of solids.⁴⁴ In the future, excitation using shaped rf pulses has the potential for improving experimental implementation of the MQ experiment.⁴⁵ In practice, rectangular pulses with $t_p \leq 3 \mu\text{s}$ and eight-pulse cycle times t_c , of 30 – $72 \mu\text{s}$ are generally employed, and the experiment is carried out on resonance.

4 MEASURING MQ INTENSITIES

Although MQ coherences have sometimes been detected directly by CW NMR,²² MQ coherences cannot be detected directly by FT NMR. Since MQ intensities are nonlinear under CW experiments, two-dimensional NMR experiments are currently employed for this purpose. Only an overview of the required experimental procedure is provided below. Additional descriptions can be found in Yen and Pines,¹ Baum et al.,² Baum and Pines,³ and Gleason.²¹

As in most two-dimensional NMR experiments, there are four distinct periods: preparation, evolution, mixing, and detection. During the preparation period, of length τ and phase ϕ , MQ coherences are excited as a result of homonuclear dipole couplings, and nonzero intensity is developed in the off-diagonal elements of the density matrix [equation (9)]. However, no observable magnetization from these elements can be detected experimentally. These coherences evolve during t_1 , the evolution period time. The mixing period of length τ (identical to the preparation period length) and phase $\phi = 90^\circ$, converts MQ coherences in the off-diagonal elements back into diagonal elements, corresponding to z magnetization. Finally, the detection period is used to create observable signal $S(\phi, \tau)$.

In order to resolve the various n quantum coherences, the phase of the preparation period ϕ is changed from 0 to 360° in increments of $\Delta\phi$, while the preparation period length, the mixing period length, and the phase of mixing period are held fixed. Fourier transformation of this series of $S(\phi, \tau)$ at constant τ with respect to ϕ yields the intensities of the n quantum orders $I_n(\tau)$. At least $2n$ phase shifts must be performed when detectable n quantum intensity is present. Fewer phase shifts will alias high-order coherence intensity to lower values of n . Most commonly, $\Delta\phi$ is set at 5.6° or 2.8° , allowing detection of $|n| \leq 16$ and 32 , respectively.

In order to determine the local distribution of nuclei within a sample, $I_n(\tau)$ is measured for a series of τ . Generally,

$\tau = n_c t_c$ which corresponds to changing the integer number of repetitions n_c , of the basis eight-pulse MQ subcycle for $\hat{\mathcal{H}}_{yx}$. In a given sample, longer τ values correspond to probing the dipolar network over increasing distances.

The length of the evolution period t_1 can also be incremented, allowing MQ coherences to evolve under the internal Hamiltonian of the spin system, yielding the n quantum coherence lineshapes.¹ However, for many applications, only the integrated intensity of the coherence is required. Thus, the evolution period time t_1 is often set to zero,^{5,46} maximizing the final signal intensity and significantly decreasing acquisition time. This also eliminates the effects of couplings linear in $\hat{I}_z$ such as chemical shift and heteronuclear dipole coupling during the evolution period.

When $t_1 = 0$ and relaxation effects are neglected, the density matrices at times 0 and 2τ are identical when $\phi = 0^\circ$ or 180° , so called ‘time reversal’. At other ϕ some transverse magnetization will also be present at the end of the mixing period and the magnitude of z magnetization will be reduced. Thus, prior to the detection period, a delay which is long compared to T_2 but short compared to T_1 allows for decay of any transverse magnetization transients. Then, a $\pi/2$ pulse can be applied to detect $S(\phi, \tau)$. Spin locking with periodic sampling can be employed during the detection period to enhance the signal-to-noise ratio of $S(\phi, \tau)$.

5 SMALL DIPOLE COUPLED NETWORKS

Even when the number of dipole coupled spins is small, the dynamics of MQ coherence growth can become quite complicated. The simplest possible system to consider is isolated pairs ($N = 2$) of spin- $\frac{1}{2}$ nuclei with identical internuclear separations and orientations with respect to the external magnetic field. Thus, all intrapair dipole coupling constants R are identical and much stronger than any interpair coupling. Then, even order selective excitation by $\hat{\mathcal{H}}_{yx}$ allows only the zero quantum and ± 2 quantum intensity to develop as given by the analytical solution to equation (5):

$$I_2(\tau) = I_{-2}(\tau) = \frac{1}{2}[1 - I_0(\tau)] = \frac{1}{2}[1 - \cos(R\tau)] \quad (10)$$

In the absence of relaxation, the oscillatory exchange of MQ coherence intensity between the orders will continue indefinitely.³⁸

In a macroscopic NMR sample, such as a single crystal or a liquid crystal, identical orientations of internuclear vectors with respect to the external magnetic field can occur. By contrast, polycrystalline powders are the most commonly used samples for MQ NMR. Even for isolated pairs with identical internuclear spacings, the angular dependence of the dipolar coupling interaction leads to destructive interference among the characteristic frequencies which contribute to the MQ intensity development, leading to steady state values of I_n at long τ .

The appearance of oscillations which are damped at long times is characteristic of the powder average of a small number of coupled spins.⁴¹ Figure 2 shows the ^{19}F MQ coherence development for sodium triflate salt ($\text{NH}_4^+\text{CF}_3\text{SO}_3^-$) well dispersed in polyhydroxystyrene.¹⁹ Only the $n = 0, 2$, and -2 quantum orders have nonzero intensity under the even-selective MQ excitation employed. This is the same behavior

Figure 2 The ^{19}F zero quantum and +2 and -2 quantum intensities from an even-selective experiment on 2 wt.% $\text{NH}_4\text{CF}_3\text{SO}_3^-$ in poly(*p*-hydroxystyrene). The salt is well dispersed in the polymer, and thus its CF_3 group behaves as expected for $N = 3$. Oscillations are distinct at early τ and destructive interference leads to steady-state values at long τ . (Reproduced by permission of the American Chemical Society from Limb et al.¹⁹)

expected for an isolated network of three dipole coupled ^{19}F nuclei, where only even MQ orders with $|n| \leq 3$ develop. This result indicates that the average spacing between the salt anions is large, allowing its CF_3 group to act as an isolated $N = 3$ cluster. Note that this configuration can be represented by the density matrix shown in Figure 1. Furthermore, the development of ± 2 quantum coherence intensity indicates that the time average of the intraion dipole couplings is nonzero. Thus, the triflate anion is not reorienting rapidly and isotropically within the polymeric matrix.

Clear oscillations in the MQ intensities are initially observed in Figure 2, while steady state is approached at $\tau > 500$ ms. The observed long time values are 0.78 for the zero quantum coherence and 0.22 for the sum of the +2 and -2 quantum coherences. These values differ significantly from the predictions of equation (6a), utilizing $N = 3$ and $C = 2$, of 0.625 and 0.375, respectively. This difference shows that the statistical limit has not been achieved, a problem that was anticipated for very small numbers of coupled spins due the presence of symmetry disallowed MQ transitions. Thus, it is desirable to determine N for very small networks by detecting the highest order coherence present, rather than by assuming that the statistical limit holds.

For larger groups of spins, good agreement with the statistical limit behavior has been found. The liquid crystal, *p*-hexyl-*p*'-cyanobiphenyl ($\text{C}_{19}\text{H}_{21}\text{N}$) is a finite cluster of dipole coupled spins, since translation and anisotropic rotation serve to destroy intermolecular dipole couplings, while intramolecular dipole couplings maintain nonzero values. As expected, the positive order MQ coherences grow with τ until all the protons on the liquid crystal molecule are coupled on the experimental timescale. No further increase occurs as the preparation time increases further. The distribution of the steady state MQ intensities is well described by equation (6b)

with $N = 20 \pm 1$. This result is in excellent agreement with the known structural formula.³

Thus, MQ NMR gives quantitative information on the number of nuclei in a limited network of dipole, when the structure is unknown. For instance, the size of small hydrogenated defects in amorphous semiconductors has been determined.^{4–7} The clustering of molecules inside zeolites^{9,11–14} and the distribution of molecules on catalysts^{8,10,29} and on chromatographic supports¹⁵ have also been investigated using the MQ spin counting technique.

6 LARGE DIPOLE COUPLED NETWORKS

Although the MQ dynamics of spin systems for which the dipole coupling network extends beyond the typical 1–2 nm length scale of a MQ NMR experiment are nearly impossible to calculate exactly, similar development of $I_n(\tau)$ is observed in many samples. Figure 3 shows the development of positive even-order MQ coherence intensity for CaF_2 powder for increasing τ created from integral multiple repeats of t_c between 30 and 60 μs . The smooth MQ development in Figure 3 is a result of the distribution of dipole coupling present in this polycrystalline sample. Significant oscillations in $I_n(\tau)$ can be seen in a single crystal CaF_2 with its (111) direction oriented perpendicular to the applied magnetic field (Figure 4). For this configuration, all internuclear vectors to the nearest ^{19}F neighbors are at either 54.7° , the magic angle, or $(54.7 + 180)^\circ$. Thus, all four dipole couplings between nearest neighbors are zero for this configuration. The strongest couplings in this system are actually between next nearest neighbors. The lack of angular dispersion and relative weak dipole couplings lead to only slow damping of the oscillation of the MQ coherences which arises from the even weaker dipolar coupling to neighbors in other shells. The small dipolar couplings in the (111) oriented crystal also lead to slower growth of positive MQ intensities than is observed for the powdered CaF_2 sample.

The observed distributions of $I_n(\tau)$ for polycrystalline powders are often described empirically as a Gaussian distribution, as can be seen in Figure 5 for powdered CaF_2 and GaP , where the solid lines are given by equation (7). The slow development of MQ coherence intensity in GaP allows the comparison to be made for low $N(\tau)$ while CaF_2 provides information at higher $N(\tau)$ values. This description is convenient, as the single parameter $N(\tau)$ can be used to

Figure 3 Even-order selective ^{19}F MQ spectra of a polycrystalline powder of CaF_2 . As τ increases, high-order coherence intensities grow monotonically

Figure 4 Even-order selective ^{19}F MQ spectra of a single crystal of CaF_2 oriented with its (111) direction along the external magnetic field. The lack of angular orientation distribution, as compared to the powder (Figure 3), leads to oscillatory growth of the zero and two quantum coherences, while the smaller magnitude of the dipole couplings in this sample leads to slower higher order coherence growth

Figure 5 Gaussian distribution (—) and experimentally measured intensities versus $N(\tau)$ for two large dipole coupled networks, Ca^{19}F_2 (squares) and Ga^{31}P (other symbols), showing reasonable agreement for $N(\tau) < 70$: (■) I_0 , (□) I_2 , (▲) I_4 , (△) I_6 , (●) I_8 , (○) I_{10}

describe an entire MQ spectrum.² However, the interpretation of $N(\tau)$ via equation 6.76 is not straightforward, since the number of coupled spins is ill defined in this situation. Materials with the highest dipolar couplings also display the fastest growth of $N(\tau)$. Thus $N(\tau)$ has been considered as a parameter that is dependent on the size, structure, and motion of the dipolar coupling network.

Non-Gaussian behavior of the distribution of positive MQ orders for infinite spin systems at long τ has been noted, usually becoming significant when $N(\tau)$ is greater than about 70. In addition, a least-squares fit to equation (6) underpredicts the intensity of the nonzero orders while overpredicting the zero quantum intensity. This may indicate relaxation of intensity in the off-diagonal density matrix elements back to diagonal elements. These effects are not seen in the 21-spin system, liquid crystal *p*-hexyl-*p'*-cyanobiphenyl ($\text{C}_{19}\text{H}_{21}\text{N}$), experiments at similar τ , and thus cumulative pulse errors cannot be the sole cause of the deviation. Experimentally,

Figure 6 Effective number of correlated nuclei, $N(\tau)$ as function of τ for three-dimensional distributions (a): ($\square$) CaH_2 (^1H),³¹ (Δ) adamantane (^1H),³¹ ($\circ$) sodium bicarbonate (^1H),³¹ (+) GaP (^{31}P).²¹ (b) All ^{19}F :¹⁶ (+) CaF_2 , ($\blacktriangle$) NaAsF_6 , ($\bullet$) CsF , ($\blacksquare$) $(\text{C}_6\text{F}_5)_3\text{SAsF}_6$. (c) A universal MQ growth curve is seen for all the samples in (a) and (b), when a nondimensional time axis is created by multiplying τ by $M_2^{1/2}$ (equation (1))

the zero quantum intensity deviates from Gaussian behavior at the smallest number of correlated spins, making it a strong indicator of the onset of relaxation effects.

However, as shown in Figure 6(a) and 6(b) for $N(\tau) < 70$, $N(\tau)$ does grow as the MQ excitation time τ increases. This development of $N(\tau)$ can be described by a universal growth curve when a dimensionless MQ excitation time is created

by multiplying τ by $M_2^{1/2}$.^{18,21,31} The result of this scaling is shown in Figure 6(c), where $M_2^{1/2}$ has been calculated from equation (1) using the known crystal structures of the materials. The solids represented in Figure 6 fall into one of two categories. In both categories the dipolar field at each nucleus in a three-dimensional crystal lattice is equivalent and time independent on the MQ timescale. For the first class of materials, no translation or rotation occurs on the NMR timescale. Examples of this category include Ca^1H_2 , Ca^{19}F_2 , and Ga^{31}P . In the second class, rapid isotropic rotation exists in the absence of translation, allowing only intermolecular dipole couplings to survive. Examples of such behavior are ^1H in adamantane or ^{19}F in salts containing hexafluoroarsenate anions (AsF_6^-). For this second category, the high concentration of NMR active nuclei with relatively low dipole couplings allows larger numbers of spins to be correlated before relaxation effects become significant.

The MQ dynamics of many molecular solids do not follow the universal growth curve, since these solids possess a variety of short internuclear spacings and motion which is neither fast nor isotropic. Sometimes, lowering the sample temperature can eliminate such undesirable motion. In addition, some nuclear distributions are inherently nonuniform, and non-Gaussian intensity distributions are observed even at short τ . For example, both isolated salt molecules and salt aggregates can exist within the same salt/polymer mixture.^{17,19} The fraction of each environment can be quantitated by treating the observed MQ spectra as a linear combination of the two MQ intensity distributions. Treatment of MQ coherence growth from nuclei within tightly coupled clusters in addition to slower intercluster growth has also been used to analyze proton distributions in amorphous hydrogenated semiconductors⁴⁻⁷ and to characterize the distribution of molecules absorbed in zeolites.^{11,12}

7 DIMENSIONALITY OF A NUCLEAR SPIN DISTRIBUTION

Certain deviations from the MQ universal behavior [Figure 6(c)] for large dipole coupled networks cannot be accounted for by the presence of molecular motion. Such deviations may indicate that the nuclear distribution is not three dimensional. Hydrogen existing on the surface of a treated natural diamond powder is an example of a two-dimensional distribution.³¹ For the diamond powder, the $N(\tau)$ versus τ curve exhibits a concave upward shape, unlike $N(\tau)$ for the 21-spin liquid crystal, which saturates at large preparation times. Thus, the diamond powder represents a large dipole coupled network. However, its MQ growth does not follow the universal scaling behavior of the three-dimensional model compounds. Even greater deviation from the universal curve was found for the initial MQ growth among protons in hydroxyapatite which provides a pseudo-one-dimensional distribution of spin- $\frac{1}{2}$ nuclei.³³

To predict the influence of dimensionality on the rate of MQ coherence in large dipolar networks, a solution to equation (4) is required. For this purpose $\hat{\rho}(\tau)$ is expanded in terms of product operators, as an alternative to tracking the time development of each of the 4^N individual elements.⁴¹ These product operators are formed from the multiplication

of individual spin operators ($\hat{I}_{iz}$, $\hat{I}_{i+}$ or $\hat{I}_{i-}$) from M of the N nuclei in the dipole network. For example, $\hat{I}_{5z}\hat{I}_{6-}\hat{I}_{7+}\hat{I}_{8z}$, represents $M = 4$ possible product operators when $N \geq 8$.

Two simplifications³¹ allow $\hat{\rho}(\tau)$ to be approximated by an expansion requiring only N coefficients:

$$\hat{\rho}(\tau) \approx \sum_{M=1}^N C_M(\tau) \hat{P}_M \quad (11)$$

Here, $\hat{P}_M$ is a time independent average product operator, representing all the possible product operators containing M spins. Thus, the time evolution of the MQ coherence and multiplicity of all possible product operators with respect to M is contained in the coefficients $C_M(\tau)$.

When $\hat{\rho}(0) = \hat{I}_z$, only $C_1(0)$ has nonzero intensity. Intensity develops in C_M for $M > 1$ with increasing τ through the commutator obtained when equation (11) is substituted into equation (4) under excitation by $\hat{\mathcal{H}}_{yx}$:

$$\begin{aligned} \sum_M \left(\frac{dC_M}{d\tau} \hat{P}_M \right) \\ = \frac{-i}{4} \sum_M C_M \left\{ \sum_i \sum_{j \neq i} R_{ij} [\hat{P}_M, (\hat{I}_{i+}\hat{I}_{j+} - \hat{I}_{i-}\hat{I}_{j-})] \right\} \quad (12) \end{aligned}$$

This summation represents only N coupled differential equations, thus significantly reducing the volume of calculation required compared to the exact solution. Information on the order of the MQ coherences has been averaged away. However, approximating the effective spin correlation size $N(\tau)$ as the center of mass of the distribution of C_M over M allows the results of the average product operator model to be compared directly with experimental measurements of $N(\tau)$.³¹

To emphasize that the rate of MQ coherence development through equation (12) is strongly dependent on the geometry of the dipole coupled network, only two values of R_{ij} will be considered. All nearest neighbor dipole couplings are taken to be equal to the root-mean-square value over the powder average for the nearest neighbor separation, and all R_{ij} for all non-neighboring nuclei are set equal to zero. This is a stepwise approximation to the true decay in the magnitude of dipole coupling constants with internuclear distance cubed.

Because R_{ij} is nonzero only for nearest neighbors, only product operators representing M spins occupying a contiguous region of space will contribute to the average product operator $\hat{P}_M$. For simplicity, lines, squares, and cubes are the shapes assumed to be associated with $\hat{P}_M$ for nuclei distributed uniformly over one-, two-, and three-dimensional lattices, respectively. A schematic drawing of $\hat{P}_9$ for a two-dimensional (surface) distribution of nuclei is shown in Figure 7. In order to compute MQ dynamics, the commutator in equation (11) must be evaluated. Only adjacent ij spin pairs need to be considered because only these have nonzero values of R_{ij} . Thus, the larger the number of nearest neighbors, the greater the possibilities for high-order MQ development. As shown in Figure 7, the spin pair ij and the M spins comprising $\hat{P}_M$ will have zero, one, or two of their spins in common; these cases correspond to pairs external to, at the surface of, or internal to $\hat{P}_M$, respectively. The commutator for external pairs is

Figure 7 Schematic drawing of $\hat{P}_M$, the average product operator for nine spins on a two-dimensional square lattice. Surface pairs lead to forward MQ growth, while internal pairs reduce the coherence size. Faster MQ coherence growth rates are anticipated as the dimensionality of the lattice increases, since the ratio of surface pairs to internal pairs increases

identically zero, resulting in no change in the size of the MQ coherence. Products of $M + 1$ and $M - 1$ spin operators result from commutators involving surface and internal pairs, respectively.

The $\hat{P}_{M+1}$ operators represent forward growth of the MQ coherence size, while the $\hat{P}_{M-1}$ operators correspond to reverse growth, allowing equation (12) to be simplified to

$$\begin{aligned} \sum_M (dC_M/d\tau) \hat{P}_M = \frac{-i}{4} \sum_M C_M \\ \times (W_{M+1}^f \hat{P}_{M+1} + W_{M-1}^r \hat{P}_{M-1}) \quad (13) \end{aligned}$$

Note that the $\Delta M = \pm 1$ selection rule for product operator evolution under $\hat{\mathcal{H}}_{yx}$ is evident from this equation. The forward and reverse growth rate coefficients W_M^f and W_M^r depend on the number of pairs at the surface of and internal to $\hat{P}_M$. Since the surface-to-volume ratio for $\hat{P}_M$ depends on its dimensionality, higher MQ growth rates are anticipated for homogeneous distributions of nuclei of increasing dimensionality.

Thus, using average product operators, an N -spin system can be represented by a set of N simultaneous differential equations, allowing the MQ dynamics of large numbers of spins, arranged in varying morphologies, to be easily simulated. Figure 8 shows the growth of $N(\tau)$ predicted by the average product operator model using only nearest neighbor couplings of 1.0 kHz. The analytical formulae used to calculate W_M^f and W_M^r in equation (13) are given in Levy and Gleason.³¹ The three curves were obtained by considering 2500 nuclei arranged uniformly on linear, square, or cubic lattices. As expected, the three-dimensional configuration of nuclei yields the fastest MQ growth. The linear geometry yields slow linear growth of $N(\tau)$. The model can be used to simulate the MQ dynamics of various types of spin distribution and has been extended to nuclear distributions having more than one characteristic nearest neighbor dipole coupling.³¹

The model and experimental data can be compared by scaling the time axis in Figure 7. The experimental data for CaH_2 and for hydrogenated diamond powder given in Figure 9 are in good agreement with the computer simulations of MQ coherence growth for two- and three-dimensional nuclear distributions based on the average product operator

Figure 8 Values of $N(\tau)$ predicted by the average product operator model for spin- $\frac{1}{2}$ nuclei evenly spaced on a line, square lattice, or cubic lattice. In each case, the nearest neighbor dipole coupling was fixed at 1 kHz. The most rapid growth of $N(\tau)$ results for the cubic lattice which has the largest number of nearest neighbors, while the linear arrangement, with the lowest number of nearest neighbors, yields the slowest development of $N(\tau)$. (Reproduced by permission of NMR Concepts from Gleason²¹)

model with only one adjustable parameter. In addition, the initial MQ growth of the pseudo-one-dimensional distribution of protons in hydroxyapatite has been found to agree with the slow, nearly linear growth predicted by the results of the product operator calculation for the one-dimensional distribution of nuclei.³³

8 RELAXATION AND EFFECT OF MOLECULAR MOTION

MQ relaxation rates have been considered in detail by Ernst in terms of the Redfield formalism.³⁵ The zero quantum and

Figure 9 Comparison of MQ dynamics predicted by average operator theory and experimental data for infinite two- and three-dimensional systems. (Reproduced by permission of the American Chemical Society from Levy and Gleason³⁰)

$n \geq 2$ MQ relaxation rates provide information on the spectral densities of autocorrelation and cross-correlation functions which is not obtainable from the more traditionally measured single quantum relaxation rates. Since the sensitivity to static magnetic field inhomogeneity is proportional to the MQ order, this effect can be problematic when measuring higher order MQ relaxation rates. However, zero quantum relaxation rates have the desirable property of not being influenced by such gradients. This exact theoretical treatment of MQ relaxation has been applied to the external paramagnetic relaxation of two spin- $\frac{1}{2}$ nuclei in a liquid³⁵ and of an oriented CH_3 group in a liquid crystal.³⁶ However, application of this exact theory becomes increasingly difficult as the size of the coupled spin- $\frac{1}{2}$ network increases and when the results must be averaged over many possible orientations. Thus, although general considerations have been addressed,^{23,28} the measurement and quantitative analysis of MQ relaxation in polycrystalline solids have been limited to date.

Empirically it has been observed that the total signal present in the detection period after MQ excitation of a rigid solid decreases with τ , often becoming negligible for $\tau > 1$ ms. The largest number of spins correlated is thus generally limited to between 100 and 1000, corresponding to a 1–2 nm length scale in a bulk three-dimensional solid. In addition, models for the growth of MQ coherence are difficult to validate because spin correlation data are generally only available for relatively very short τ .

Additional effects are observed when molecular motion modulates the dipolar couplings in solids through variations in internuclear distances and/or the orientation of the internuclear vectors with respect to the applied magnetic field.²⁰ When the timescale for motion is comparable to τ , complete time reversal of the preparation period is not achievable during the mixing period. Thus, the fraction of magnetization which is actually refocused by the MQ experiment f_{MQ} will generally be < 1 . However, efficient refocusing can occur if the frequency of the molecular motion and the MQ experiment are matched correctly. Since τ is generally between 30 μs and 1 ms, motions with frequencies between 1 and 33 kHz can be probed. Since MQ coherences can involve anywhere from 2 to >100 nuclei, the correlated motion for atomic groups of various sizes can be probed, rather than tracking the motion of a single site.

As temperature is monotonically increased and the MQ preparation time is fixed, the frequency of motion can take on several of these special refocusing frequencies, interspersed by defocusing frequencies. Thus, a series of oscillations in f_{MQ} with temperature is expected. In addition to identifying the frequency of motion, the shapes of these oscillations are signatures of the underlying mechanism of molecular motion, e.g. multisite hops versus continuous rotations. Only motions which restore the relative positions of the nuclei after the MQ experiment will cause refocusing. Motions, such as translational diffusion, which do not restore the initial configuration of the nuclei will not produce refocusing under any condition.

Figure 10 shows the temperature dependent ^{19}F f_{MQ} for two polytetrafluoroethylene samples of different crystallinity.¹⁹ Each line indicates a fixed value of the MQ preparation period τ . The overall decrease in f_{MQ} with increasing τ indicates that relaxation is not associated with molecular motion. However, at each fixed τ , oscillations in f_{MQ} can be seen. Oscillations in

Figure 10 The fraction of refocused magnetization, f_{MQ} at three different values of τ as a function of temperature for *as*-polymerized (■, ▲, ●, —) and melt-crystallized (□, ○, △, - - - -) polytetrafluoroethylene. Oscillations are seen only in the *as*-polymerized polymer, corresponding to the motion of a point defect

f_{MQ} are observed from 208 to 230 K for the 98% crystalline sample, while this ratio is constant over the same temperature range for the 64% crystalline sample. These oscillations may be associated with paracrystalline defects found only in the first sample. Thus, the MQ refocusing experiment is able to differentiate clearly between polymer samples which have different thermal histories. The sharpness of the MQ refocusing features and their variations in magnitude, shape, and sign with temperature are signatures of the molecular level details of the underlying dynamics which produce them.

ABSTRACT: A unified scale is recommended for reporting the NMR chemical shifts of *all* nuclei relative to the ¹H resonance of tetramethylsilane. The unified scale is designed to provide a precise ratio, $\mathcal{E}$, of the resonance frequency of a given nuclide to that of the primary reference, the ¹H resonance of tetramethylsilane (TMS) in dilute solution (volume fraction, $\varphi < 1\%$) in chloroform. Referencing procedures are discussed, including matters of practical application of the unified scale. Special attention is paid to recommended reference samples, and values of $\mathcal{E}$ for secondary references on the unified scale are listed, many of which are the results of new measurements.

Some earlier recommendations relating to the reporting of chemical shifts are endorsed. The chemical shift, δ , is redefined to avoid previous ambiguities but to leave practical usage unchanged. Relations between the unified scale and recently published recommendations for referencing in aqueous solutions (for specific use in biochemical work) are discussed, as well as the special effects of

working in the solid state with magic-angle spinning. In all, nine new recommendations relating to chemical shifts are made.

Standardized nuclear spin data are also presented in tabular form for the stable (and some unstable) isotopes of all elements with non-zero quantum numbers. The information given includes quantum numbers, isotopic abundances, magnetic moments, magnetogyric ratios and receptivities, together with quadrupole moments and linewidth factors (where appropriate).

1 INTRODUCTION

A distinguishing feature of nuclear magnetic resonance (NMR) is that signals are isotope-specific. In other words each signal can be firmly linked to a particular element and nuclide. Two features follow: Firstly there is a close connection with chemistry and, in particular, with the Periodic Table, since almost all elements can be studied; secondly, the spin properties of each isotope need to be clearly tabulated and firmly understood. It is a principal purpose of this document to provide such information.

Any scientific discipline relies for its effectiveness upon communication of ideas and results, which can only occur if there is an agreed basis for the meaning of the terminology used. The process of communication is greatly eased if there are universally-recognized conventions for measurement and reporting of quantities with their units and symbols. The aim of this document is to set down such a set of meanings and conventions in relation to chemical shifts (and shielding) and to list resonance frequencies for reference signals for each magnetically active nucleus.

Within IUPAC, Commission I.5 has been responsible for Molecular Structure and Spectroscopy. Until now, this Commission has produced only three reports^{1–3} specifically relating to NMR. The two earlier ones of these refer to chemical shifts. The more recent of these two publications is 25 years old, and the NMR world has changed beyond recognition since then. Recently, however, conventions for chemical shifts of five nuclei of wide biochemical interest have been included in *Recommendations for the Presentation of NMR Structures of Proteins and Nuclei Acids*⁴ by Commission I.7, Biophysical Chemistry. The current document addresses the same issue for general chemical usage and extends the conventions to the entire range of active nuclei, providing a more comprehensive guide to the factors important in chemical shift referencing. A unified list of properties of NMR-observable nuclei is also included herein.

2 NUCLEAR SPIN PROPERTIES

The phenomenon of NMR is based upon the magnetic properties of various isotopes of elements in the Periodic Table. It is therefore important to have an accessible unified list of these properties. These are contained in Tables 1–3 of this article which include the following for each stable isotope and each long-lived radioactive isotope with non-zero spin:

^a Excluding the lanthanides, the actinides and most radioactive isotopes.

^b Nuclei in parentheses are considered to be not the most favorable of the element concerned for NMR.

^c Data are 'representative isotopic compositions', taken from Rosman et al.,⁸ For the error limits on the natural abundances, see Rosman et al.⁸

^d Data derived from the compilation in Mills et al.,⁶ pp. 98–104, which lists values of $\mu_{\text{max}}/\mu_{\text{N}} = \gamma\hbar I/\mu_{\text{N}}$. For the error limits, see Mills et al.⁶

^e Data from Mills et al.,⁶ pp. 98–104 (taken mostly from Pyykko²⁶ and Raghavan²⁷) and updated from Pyykko.²⁸ It should be noted that reported values of Q may be in error by as much as 20–30%. For the error limits, see Pyykko.²⁸

^f Ratio of the resonance frequency of the reference to that of the protons of TMS at infinite dilution (in practice at $\varphi = 1\%$) in CDCl₃.

^g M $\equiv$ molarity in mol dm⁻³ (solution); m $\equiv$ molality in mol kg⁻¹ (solvent). Some results from Ref.⁹ were initially referenced⁷ to a TMS concentration of 4.75 m in CDCl₃, but the values are corrected to refer to a dilute ($\varphi = 1\%$) solution of TMS in CDCl₃.

^h $\ell = (2I + 3)Q^2/I^2(2I - 1)$ (Ref.⁵). The values are quoted, arbitrarily, to 2 significant figures.

ⁱ D^P is the receptivity⁵ relative to that of ¹H whereas D^C is relative to ¹³C. The values are given to three significant figures only.

^j A useful isotope of $I = 1/2$ exists.

^k 15% by volume of BF₃·Et₂O in CDCl₃.

^l Small amount of lock substance ($\varphi \leq 10\%$) in neat liquid, except for ⁶¹Ni (where $\varphi = \text{ca. } 20\%$ of C₆D₆ is involved).

^m $\mathcal{E}$ In reasonable agreement with a value deduced from a ratio given in Ref.³⁰

ⁿ $\mathcal{E}$ Deduced from data in Ref.³¹

^o $\mathcal{E}$ Deduced from a ratio given in Ref.³²

^p Plus C₆D₁₂ ($\varphi = 10\%$) for field/frequency lock purposes.

^q Radioactive, with a long half-life.

^r Containing a little C₆D₆ ($\varphi < 10\%$).

^s With conversion factors applied by Granger.

^t The data in Ref.³⁶ are only accurate to 4 decimal places. The proposal herein is that $\mathcal{E}$ (⁸³Kr) is defined to the 6 decimal places given.

^u In CH₃CN/CD₃CN for ⁹³Nb, ¹²¹Sb and ¹²³Sb.

^v Plus a small quantity of NaOH.

^w Semi-saturated in H₂O/D₂O.

^x Plus 0.5 M DNO₃.

^y Calculated from the value for ¹²⁹Xe via the ¹²⁹Xe : ¹³¹Xe frequency ratio.

^z For the solution conditions, see the reference.

^A Value calculated from literature data on nuclear magnetic moments.

^B The proposal herein is to define to 6 decimal places, but linewidths are generally such that this is unnecessarily accurate.

^C Deduced from the ²⁰¹Hg : ¹⁹⁹Hg ratio given in Ref.⁴¹

^D The high toxicity of this compound means its direct use should be strongly discouraged.²³

^E Saturated in conc. HNO₃, then diluted with an equal volume of D₂O.

- (i) The nuclear spin quantum number, I , of the ground state of the nucleus.* This defines the magnitude of the spin angular momentum vector (and hence magnetic dipole moment – see below). The z -component quantum number is then denoted by m_I .
- (ii) The standard isotopic natural abundance, x , expressed as a mole fraction in %.
- (iii) The magnetic dipole moment, μ , of the nuclide, in terms of the nuclear magneton, μ_N . It should be noted that we have chosen to use the full vector magnitude of μ , given by:

$$|\mu|/\mu_N = |\gamma|\hbar[I(I+1)]^{1/2}/\mu_N \quad (1)$$

where γ is the magnetogyric ratio and $\hbar$ is the Planck constant divided by 2π . Many lists prefer to give only the maximum value of the z -component of μ , namely $\mu_z = \gamma\hbar I$, frequently without explicitly stating this fact. The sign of μ given in Tables 1–3 refers to its direction compared to the related spin angular momentum vector.

- (iv) The magnetogyric ratio, γ (sometimes called the gyro-magnetic ratio). The SI base units of this quantity are (angular frequency)/(magnetic induction), normally given as $\text{rad s}^{-1} \text{T}^{-1}$.
- (v) The receptivity, of a nucleus in natural abundance, which influences the NMR signal strength. A common definition⁵ involves the proportionality of receptivity to $\gamma^3 x I(I+1)$. In practice it is useful to list such receptivities relative to those of the commonly-used nuclei ^1H (proton) and ^{13}C , giving receptivity ratios D^P and D^C respectively. Both these quantities are given in Tables 1 and 2.
- (vi) The quadrupole moment, Q , for nuclei with spin quantum number $I > 1/2$ (Tables 2 and 3 only). These data fall naturally in the region of 10^{-30} m^2 , i.e., fm^2 . However quadrupole moments are often expressed in units of 10^{-28} m^2 , called a barn, where $1 \text{ barn} = 100 \text{ fm}^2$.
- (vii) The line-width factor, ℓ , for quadrupolar nuclei. This is defined⁵ by:

$$\ell = Q^2(2I+3)/[I^2(2I-1)] \quad (2)$$

When taken in conjunction with the relative receptivity (e.g., as D^C/ℓ), this quantity gives a guide to the ease with which spectra can be obtained for different quadrupolar nuclei in solution for similar site symmetries and molecular mobilities. However, in practice, both symmetry and mobility may vary widely, thus introducing variations that may amount to several powers of ten.

Table 1 gives the data for the spin-1/2 nuclei in the Periodic Table, whereas Table 2 refers to quadrupolar nuclei. These two tables omit the lanthanide and actinide nuclei, which are separately listed in Table 3. Many of the data in Tables 1–3 have been taken from the IUPAC ‘Green Book’,⁶ but additional information is included (particularly on resonance frequencies and quadrupole moments). A version of Tables 1–3 has been published.⁷ However, the tables given here contain revised

resonance frequencies for consistency with the recommended primary reference, as described in Section 3.5. In addition, some new measurements of resonance frequencies are reported in Tables 1–3, and information about solution conditions and relevant references has been added.

3 CHEMICAL SHIFTS

3.1 Background

Since the discovery of the chemical shift in 1950, NMR spectroscopy has become of vital importance to chemistry and related disciplines. The term chemical shift refers to a difference in resonance frequency (conventionally expressed as a fraction – see below) between nuclei in different chemical sites (or for samples under different physical conditions). Such effects are caused by variations in shielding by the electronic environment of the nuclei in question, and the concept of chemical shift is described by equation (3):

$$\nu = \frac{\gamma}{2\pi} B_0(1 - \sigma) \quad (3)$$

In this equation, the resonance frequency ν (normally in the radiofrequency region) is related to the applied magnetic flux density B_0 by the magnetogyric ratio of the nucleus and the shielding constant σ . In the SI, ν is expressed in hertz, Hz, (and is normally in the range of tens or hundreds of MHz), B_0 is in tesla, T, and σ is a dimensionless fraction (generally reported in parts per million, ppm). Equation (3) is usually applied to the situation in isotropic media (liquids, solutions and gases), for which σ can be represented as a scalar quantity. However, the value of σ depends on molecular orientation in the applied magnetic field and can be represented by a scalar quantity only because of the averaging caused by rapid isotropic molecular tumbling. Therefore, σ is a second-rank tensor and must be used in that form for many situations in the solid state and in liquid crystals (and their solutions).

Whereas frequencies can be measured very precisely, the same cannot be said of B_0 . Thus, although in principle chemists would like to know the absolute value of σ , it has long been recognized that only relative values can normally be obtained with precision. Therefore, from the early days of NMR the concept of a standard reference signal has been developed. This requires a number of choices, among which are:

- (i) whether to base chemical shifts on resonance frequencies or on shielding
- (ii) which compound to use as a reference
- (iii) what further conditions to specify for the reference situation
- (iv) whether to use separate references for different nuclei or to attempt to link them.

These matters will be dealt with in detail below.

In the early days of NMR, resonance was normally achieved by varying the applied field B_0 . It therefore seemed natural for positive chemical shifts to refer to situations where the sample resonated at higher field than that of the reference. Equation (3) shows that this corresponds to greater shielding for the sample than for the reference – a convention that was popular with theoreticians, who are principally concerned

*NMR is entirely concerned with the nuclear spin in the lowest-energy nuclear state, though Mössbauer spectroscopy involves values of I in higher-energy nuclear states.

Table 3 The spin properties of lanthanide and actinide nuclei^a

Isotope	Spin	Natural abundance <i>x</i> /%	Magnetic moment μ/μ_N	Magnetogyric ratio $\gamma/10^7 \text{ rad s}^{-1} \text{ T}^{-1}$	Quadrupole moment ^b Q/fm^2	Frequency ratio ^c $\Xi/\%$

^fReference: UF₆(with $\varphi = 10\%$ of C₆D₆).⁴³

with σ . The first clear consensus on an experimental reference compound for proton NMR (by far the most popular nucleus at the time because of its high sensitivity) was tetramethylsilane (TMS), introduced in 1958 by Tiers.⁴⁴ However, both for proton NMR and for other nuclei various chemical shift scales were used, with some increasing in the direction of increasing magnetic field and others increasing in the direction of decreasing field (which corresponds to increasing frequency).

The convention recommended by IUPAC in the 1972 document,¹ which mostly concerned proton NMR, was that given in equation 4:

$$\delta_{X,\text{sample}} = \left(\frac{\nu_{X,\text{sample}} - \nu_{X,\text{reference}}}{\nu_{X,\text{reference}}} \right) \times 10^6 \quad (4)$$

in which the chemical shift of a resonance for nucleus X is defined. For protons referenced to TMS this convention gives positive values with increasing frequency, and most proton chemical shifts then turn out to be positive. A second IUPAC report² in 1976 extended the recommendations to include nuclei other than protons, always with a high-frequency-positive convention.

Of course, since σ is, in principle, a tensor quantity, so is δ . However, the present document deals only with the isotropic average value of δ , which is the usual value of relevance for solution-state NMR. The tensor properties of σ and δ may be the subject of a later document.

3.2 Recommendations Endorsed

At this point it is appropriate to list those recommendations of the previous two IUPAC reports on NMR which relate to chemical shifts^{1,2} (including presentation of spectra) and which we endorse, with one exception noted under item 6. These relate to notational matters and are particularly directed at publications in chemical journals. In several places we use different wording from the original reports and in some cases extended meanings:

1. The nucleus giving rise to the spectrum concerned should always be explicitly stated in full or in abbreviation (e.g., ¹⁰B NMR or boron-10 NMR). The isotopic mass number should be given except in cases without ambiguity. In the case of hydrogen NMR the *de facto* usage is proton NMR, deuterium NMR or tritium NMR, in spite of the inconsistency of the wording. Abbreviations such as PMR for proton NMR are strongly discouraged. The term multinuclear NMR is clumsy (a repeated word ‘nuclear’) and so is also to be discouraged. Where reference to a variety of nuclei is required, multinuclear magnetic resonance should be written in full.
2. The graphical presentation of spectra should show frequency increasing to the left and positive intensity increasing upwards.
3. The dimensionless scale for chemical shifts should be tied to a reference, which should be clearly stated. The procedures used must be carefully defined.

4. The dimensionless scale factor for chemical shifts should generally be expressed in parts per million, for which ppm is the appropriate abbreviation. The radiofrequency of the reference, appropriate to the nucleus in question and to the spectrometer in use, should always be quoted, with sufficient accuracy in relation to the numerical values of shifts listed. Unfortunately, older software supplied by manufacturers to convert from frequency units to ppm in FT NMR sometimes uses the carrier frequency in the denominator instead of the true frequency of the reference, which can lead to significant errors.
5. The chemical shift scale should be defined with respect to resonance frequencies, with the appropriate sign convention (i.e., a positive sign should imply the sample resonates to high frequency from that of the reference). In order to avoid ambiguities of sign, the term ‘chemical shift’ should *not* be used to describe variations in shielding.
6. The symbol δ (lower case Greek delta) should be used for chemical shift scales with the sign convention given above. Such a symbol should *never* be used to refer to shielding. These recommendations cohere with the definition of the δ -scale adopted in References.^{1,2} The definition of δ in equation 4 leads to a value with no units, and the 1972 document recommended that ‘ppm’ be not stated explicitly (e.g., $\delta = 5.00$, *not* $\delta = 5.00$ ppm). However, this convention is widely ignored. Therefore we do *not* endorse the omission of ‘ppm’ in reporting values of δ (see Section 3.3).
7. The nucleus in question should be indicated as a subscript or in brackets, e.g., δ_C or $\delta(^{13}\text{C})$, unless there is no ambiguity.
8. As far as possible full information should be given in publications regarding any factor that might influence chemical shifts, such as:
 - (i) The physical state of the sample (solid, liquid, solution or gas), with additional relevant facts where necessary.
 - (ii) For solutions, the name of the solvent and the concentration of solute.
 - (iii) The nature of the referencing procedure, e.g., internal, external (coaxial tubes or substitution), absolute frequency. (This aspect is discussed in detail in later sections of this article.)
 - (iv) The name of the secondary reference compound local to the nucleus in question and its concentration. Note, however, that no reference compound needs to be added to the sample if the unified scale described in Section 3.5 is used, though a chemical shift value with respect to a recommended secondary reference compound, obtained via the unified scale, may still be quoted. In exceptional cases, where an isotope-specific secondary reference compound must be used in the experimental measurement, a clear description of the referencing procedure should be given.
 - (v) The temperature and (if different from ambient) the pressure of the sample.
 - (vi) Whether oxygen and other gases have been removed from the sample.
 - (vii) Any chemicals present in the sample, in addition to the solvent and the compound under investigation, and details of their concentrations.

3.3 Definition and Reporting of δ Scales

As mentioned above, the IUPAC Recommendation¹ dating from 1972 defined the proton chemical shift scale in such a way that δ has no quoted units but is presumed to be in ppm. However, this recommendation not to use ‘ppm’ has *not* received acceptance in practice. It is a simple matter to rewrite equation 4 in a general way that can lead validly to the units of ppm. We now *define* the chemical shift (for any nucleus X, using its local reference substance) by equation 5:

$$\delta_{X,\text{sample}} = (\nu_{X,\text{sample}} - \nu_{X,\text{reference}}) / \nu_{X,\text{reference}} \quad (5)$$

that is, *without* the factor of 10^6 . This leads, in general, to a very small number, $M \times 10^{-n}$. Normal practice has been and will doubtless continue to be to use $n = 6$ and thus to express δ in ppm. With equation 5 as the *definition* of δ , equation 6 provides a simple procedure for *calculating* the value of δ in ppm from measured frequencies:

$$\delta_{X,\text{sample}}/\text{ppm} = \frac{(\nu_{X,\text{sample}} - \nu_{X,\text{reference}})/\text{Hz}}{\nu_{X,\text{reference}}/\text{MHz}} \quad (6)$$

where the factor of 10^6 difference in the units of numerator and denominator is appropriately represented by the units ppm.

This re-definition allows values to be quoted also in parts per billion, ppb = 10^{-9} , (as is appropriate for some isotope effects) by expressing the numerator in equation 6 in millihertz (mHz). Alternatively, the units of equation 6 could be altered to give % (relevant for some heavy-metal chemical shifts), but ppm will undoubtedly remain as the most common usage. *IUPAC therefore recommends that the chemical shift δ be defined by equation 5 and that δ normally be expressed in ppm.*

3.4 Referencing Procedures

Accurate and consistent referencing is easy to visualize but hard to implement. For mobile isotropic media (liquids, solutions and gases) there are several possible methods:

- (a) *Internal referencing*, where the reference compound is added directly to the system under study. This method is used almost universally for ^1H and ^{13}C NMR. However, it is clearly limited by the solubility, miscibility or mutual reactions of the sample components and may be difficult to implement for many samples in which a variety of nuclei are studied.
- (b) *External referencing*, involving sample and reference contained separately in coaxial cylindrical tubes. A single spectrum is recorded, which includes signals from both the sample and the reference compound.
- (c) *Substitution method*: The use of separate cylindrical tubes for the sample and reference compound, with (in principle) spectra recorded individually for each. It is similar to external referencing in that sample and reference materials are not mixed, but there are significant differences in the two procedures, as described later, which arise because of the common use of precise field/frequency locking (usually *via* the ^2H signal of a deuterated solvent). If locking is not used, the magnet should not be re-shimmed between running the sample and reference solutions, since this changes the applied magnetic field.

- (d) Referencing *via* direct measurement of the absolute frequency of the field/frequency lock signal, usually provided by the ^2H resonance of an internally-contained deuterated compound (frequently the solvent). This method is discussed more fully in Section 3.6.
- (e) Application of magic-angle spinning, usually with the substitution method, but also conceivably with coaxial tubes – see Section 3.8.

These methods all have various advantages and disadvantages. For (a) the shielding of the reference nucleus depends, to a greater or lesser extent, on the solvent, on the solute under study, and on the concentration of both solute and reference because of the effects of intermolecular interactions. These effects may be minimized by a judicious choice of solvent and reference compound, but they cannot be eliminated. External reference procedures (b) generally require corrections arising from differences in bulk magnetic susceptibility between sample and reference. These corrections depend on the geometry employed for the sample containers. For the usual coaxial cylindrical arrangement, the correction is⁴⁵

$$(\delta_{\text{true}} - \delta_{\text{obs}}) = k(\kappa_{\text{sample}} - \kappa_{\text{reference}}) \quad (7)$$

where κ refers to the relevant volume magnetic susceptibility (in rationalized units) and ideally $k = +1/6$ for a tube perpendicular to B_0 , $k = -1/3$ for a tube parallel to B_0 (as is usual for a superconducting magnet), and $k = 0$ for a tube inclined at the magic angle. These theoretical factors are calculated for infinite cylinders. In practice they depend on the length of the liquid column and other geometrical factors which are not always under control. No correction is needed for spherical samples, but the production of a truly spherical sample cell is generally not feasible. (Equation 7 is consistent with SI notation. A corresponding expression in the cgs system would substitute $k_{\text{cgs}} = 4\pi k_{\text{SI}}$ along with a $\Delta\chi_V$ term numerically equal to $\Delta\kappa/4\pi$. Many listings of susceptibility data give χ_V rather than κ .)

The substitution method uses the fact that, with the advent of stable, internally solvent-locked spectrometers, it has become feasible to obtain accurate data by measuring the spectra of sample and reference in two separate experiments. If the sample and the reference compound are each dissolved in the same solvent at low concentration (which, where feasible, we recommend), the substitution method is equivalent to use of an internal reference except that the reference substance does not contaminate the sample or interact with it, chemically or physically. If the reference compound is a nearly neat liquid with only a small amount of the deuterated ‘solvent’ to serve as a lock, the measured chemical shifts may be slightly different from those obtained with an internal reference because of differing molecular interactions. It might appear that a magnetic susceptibility correction would be needed if the susceptibilities of sample and reference differ, but this is not the case. With the field/frequency lock established via the deuterated solvent, the applied magnetic field simply shifts slightly to maintain the magnetic induction inside the sample tube constant so as to keep the ^2H nuclei on resonance. There is thus a distinct difference between the commonly used *internally locked* system, in which the magnetic induction B_0 is maintained constant and an *unlocked* (or *externally locked*) system in which the applied field H_0 is constant.

If the lock signal of the sample differs from that of the reference, a lock correction may need to be applied according to:

$$\delta_{\text{true}} = \delta_{\text{measured}} + \left(\delta_{\text{sample}}^{\text{lock}} - \delta_{\text{reference}}^{\text{lock}} \right) \quad (8)$$

Except for very strongly hydrogen-bonded systems,^{46–48} no primary isotope effects between proton and deuterium have been firmly established, and none are expected on theoretical grounds. Hence, the difference between deuterium lock frequencies in equation (8) may be obtained from a table of proton chemical shifts. However, when polyhydrogenated groups are involved, corrections may be needed for secondary isotope effects⁴⁶ arising from $^1\text{H} \rightarrow ^2\text{H}$ replacement. When high precision is required, the measurement of the shift difference between the locks may be obtained via direct observation of the deuterium spectrum of the two solvents, placed in coaxial tubes.

However, for most modern spectrometers the manufacturers have incorporated compensating procedures for lock changes, largely for the users’ convenience of retaining the spectral window in the same position on the screen or chart. Unfortunately these procedures vary between manufacturers and between spectrometers of different ages from the same manufacturer, so no completely general comments on this question can be made here. NMR spectroscopists must refer to the relevant operating manual for details. In most cases with modern instruments the effect is to keep the magnetic field inside the samples constant when different lock compounds are used. In such situations the correction term in brackets in equation 8 is not necessary. Of course, the accuracy of the result clearly depends on what the manufacturers use for the term in brackets, generally present in a ‘look-up’ table in the spectrometer software. *We recommend that manufacturers give clear, explicit and accurate guidance on their procedures in this matter and quote their ‘look-up’ tables prominently.*

Another situation where isotope shifts have some effect is when signals of the reference compound are affected, for instance for ^{19}F measurements. In this case the signal is split into four lines with intensities approximately 27 : 27 : 9 : 1 because the natural-abundance isotopic ratio $^{35}\text{Cl} : ^{37}\text{Cl}$ is ca. 3 : 1. Since CFCl_3 is firmly accepted as the local reference for ^{19}F , it is not reasonable to suggest a new alternative. It is recommended that the reference signal is that of $\text{CF}(^{35}\text{Cl})_2(^{37}\text{Cl})$.

Earlier IUPAC documentation^{1,2} did not suggest any specific composition for the reference sample, or choice of solvents. Ideally, for most referencing methods, a non-polar solvent consisting of nearly spherical molecules should be used, and measurements should be extrapolated to zero reference concentration. Clearly such procedures are not generally feasible, so that caution always needs to be exercised when comparing shift data from different sources.

3.5 A Unified Scale

As NMR studies of various nuclei were initiated, each was, of necessity, treated independently, with some substance containing the nuclide being studied selected as a reference compound. The result is a vast collection of data in the literature for multinuclear magnetic resonance based on a large array of reference compounds. The proliferation of

reference substances is, however, unnecessary and in some ways unhelpful. In a given magnetic field all resonance frequencies form a single spectral range, and it is only because different nuclides resonate at markedly different frequencies that use of separate references has arisen. With modern instruments, in which all frequencies are derived from a single source, it is therefore possible to relate the observed frequencies of all nuclides in a particular sample to that of a single primary reference – preferably the proton resonance of TMS.[#]

There are, however, two reasons for wishing to retain the concept of a separate reference for each nucleus: (i) It is convenient to speak of, say, an aromatic ¹³C resonance at x ppm from the ¹³C line of TMS, rather than always quoting a frequency to many significant figures, and (ii) many data tabulations are available with values only expressed relative to separate heteronuclear references. Thus, for a unified scale to be of practical use, there must be agreed frequency relations between a set of commonly used secondary (heteronuclear) references and the primary reference. Measurements of such relations have been reported sporadically since the time of early double-resonance experiments,⁴⁹ and it has been proposed to relate the separate reference frequencies to a primary standard originally defined for a magnetic field such that the ¹H TMS signal is at exactly 100 MHz. These frequencies have been given⁴⁹ the symbol Ξ (capital Greek xi), and some tabulations have been presented.^{5,14,50–52} However, it is clearer and more appropriate for users of modern high-field NMR spectrometers simply to define Ξ as the ratio of the secondary (isotope-specific) frequency to that of ¹H in TMS in the same magnetic field. Therefore, it is convenient to express Ξ as a percentage by the use of equation 9:

$$\Xi/\% = 100(\nu_X^{\text{obs}}/\nu_{\text{TMS}}^{\text{obs}}) \quad (9)$$

where $\nu_{\text{TMS}}^{\text{obs}}$ is the measured ¹H frequency of TMS. The use of percentage ensures that values of Ξ with this recommendation are numerically identical to those based on the earlier⁴⁹ definition.

Recently, the question of a unified reference has been addressed for multinuclear studies in biomolecular NMR: Wishart et al.⁵³ surveyed the relevant literature, pointed out inconsistencies in existing practices, and proposed the use of a single internal reference – for their purposes, one that is highly soluble in water (sodium 2,2-dimethyl-2-silapentane-5-sulfonate, DSS[#], preferably deuterated at the CH₂ positions). Operationally, as discussed in the following sections, it is often easier to obtain the necessary heteronuclear frequency data directly via the lock signal than to make additional measurements with various reference materials for different nuclei.

IUPAC recommends that a unified chemical shift scale for all nuclides be based on the proton resonance of TMS as the primary reference. This recommendation is in line with

the *Recommendations for Presentation of NMR Structures of Proteins and Nucleic Acids*, recently promulgated⁴ by IUPAC in conjunction with the International Union of Biochemistry and Molecular Biology and the International Union of Pure and Applied Biophysics, which include recommended Ξ values for several nuclei of importance in such studies for aqueous solutions, but which uses the proton resonance of DSS as the primary standard because of its solubility in water (see Section 3.9).

In conformity with other areas in physical chemistry, it would be desirable to define a precise standard state – for example, pure liquid TMS or TMS at infinite dilution in CDCl₃ at 293 K and 1 bar. [Indeed, in principle a better standard might be ³He or ¹²⁹Xe in the gaseous state at a very low pressure (see Ref.⁵⁵ and references therein), but this is not practicable.] However, in this document we concentrate on aspects that are of immediate practical utility.

Temperature and pressure effects on chemical shifts for solutions and solid samples are sufficiently small for the lighter elements to be generally ignored for most chemical usage of NMR (largely carried out at ambient probe temperature and pressure), so we make no detailed recommendations regarding these parameters. References^{55,56} contain some data on the temperature dependence of ¹H and ¹³C resonances for TMS. Variation of solvent and/or change in sample concentration are known to have important effects on many chemical shifts, but they are relatively small for a symmetrical, non-polarizable molecule like TMS.

To assess the magnitude of the concentration effect, measurements have been obtained¹² of the proton chemical shift for TMS in solutions of volume fractions, $\phi = 0.01\%$, 1% and 80% in CDCl₃ (see the Appendix). The ¹H NMR frequency of TMS ($\phi = 1\%$) in chloroform is essentially at the infinite dilution level, the value for a $\phi = 0.01\%$ solution differing by of the order of $10^{-7}\%$ in Ξ , which is normally reported to only $10^{-6}\%$. However, for a $\phi = 80\%$ solution Ξ is $9 \times 10^{-6}\%$ larger than for a $\phi = 1\%$ solution. *Therefore, for the primary reference in multinuclear magnetic resonance we recommend a dilute solution (approximately $\phi = 1\%$ or less) of TMS in CDCl₃.* This recommendation does not preclude the use of TMS in other solvents as an alternative internal reference for ¹H NMR, and it is consistent with the use of DSS in aqueous solution (see Section 3.7).

These recommendations should not be taken in any way to preclude the design and implementation of experiments to measure specific properties, such as very high precision relative frequency measurements and special sample arrangements designed to minimise certain molecular interactions. Data will continue to be reported in the most effective way for the purpose at hand, but we believe that adoption of the unified chemical shift scale will facilitate comparison of the vast majority of NMR frequency measurements. The choice of the base reference as the proton signal of TMS is in accord with the virtually universal use of this signal as a reference for proton NMR.[#]

[#] TMS has a low boiling point (28 °C), which can be advantageous in facilitating removal from non-volatile samples after use, but can in other circumstances be a severe disadvantage. To overcome this problem, a substance such as [(CH₃)₃Si]₄C (m.p. 267 °C), can be used as a reference⁵⁴ and the results converted to the TMS standard.

[#] The name sodium 3-(trimethylsilyl)propane-1-sulfonate is strictly the correct one for this compound.

[#] With hindsight it might have been better to choose the ²⁹Si signal of TMS since that is arguably even less susceptible to outside influence than the ¹H resonance (silicon being at the symmetry center of the molecule). However, because of the large amount of literature based on the proton signal, we recommend that the primary reference remain the ¹H signal of TMS.

If the recommendation for use of a unified scale is widely adopted, future measurements should be reported as $\mathcal{E}$ values. However, to assure consistency with data already in the literature, it is important to have a set of $\mathcal{E}$ values of sufficient accuracy to permit conversion between the primary TMS reference and at least one secondary homonuclear reference for each nuclide (other than ^1H). Tables 1–3 list values of $\mathcal{E}$ for a number of commonly used secondary references, which are hereby recommended for further use. These values come from a number of sources, as indicated in the tables. However, it should be noted that a number of these compounds are hazardous (for example: Me_2Se , Me_2Te , $\text{Ni}(\text{CO})_4$ and, especially, Me_2Hg). The unified scale has the advantage that its use avoids direct handling of any secondary references (see Section 3.6). For most of the nuclides listed in Table 3, there are few data available, and the values of $\mathcal{E}$ are simply approximations based on magnetogyric ratios.

However, for Tables 1 and 2, values of $\mathcal{E}$ are stated for almost all nuclides to $10^{-6}\%$. For 69 of the most commonly studied nuclides, careful measurements of $\mathcal{E}$ have been made specifically for the purpose of this tabulation. The frequencies of ^{13}C and ^{29}Si were determined for samples of TMS in dilute solution in CDCl_3 .^{12,13,15} The remaining 67 measurements were made⁹ by the substitution method (as described in the Appendix). Since all observation frequencies and the ^2H lock frequency are derived from a single source, the measured frequencies ($\mathcal{E}$) are reproducible to better than $10^{-7}\%$ and are reported to $10^{-6}\%$. Experimental details are given in the Appendix. Values of $\mathcal{E}$ for the remaining 30 nuclides in Tables 1 and 2 are taken from published values, which have been converted to be consistent with the choice of the ^1H signal for TMS in very dilute solution as the primary reference. The literature cited should be consulted for details of the experimental procedure and for estimates of experimental precision and accuracy.

For ^1H and ^{13}C NMR, internal referencing has been used almost exclusively, primarily to avoid bulk magnetic susceptibility effects, which can be of the same magnitude as some chemical shift differences that are interpretable with regard to chemical structure. The recommended reference for these nuclides is therefore TMS in a dilute solution in CDCl_3 , and for consistency this reference is recommended also for ^{29}Si . For most other nuclides, magnetic susceptibility effects are small relative to chemical shift differences, and many of the published data have been reported relative to an external or replacement reference, often a neat liquid where feasible. To provide maximum utility, most of the entries in Tables 1 and 2 refer to such neat liquids or concentrated solutions, usually with a minimum amount of deuterated substance added to provide a stable lock. Of course, a very large number of such reference materials and lock substances could be used, but as described in Section 3.6, it is relatively simple to convert from one to another if necessary.

Values of $\mathcal{E}$ can generally be determined to $10^{-6}\%$, which represents resonance measurement differences of only 0.01 ppm for nuclides with large values of γ to 0.5 ppm for nuclides with very low γ values (an imprecision which is usually negligible compared with their generally large chemical shift ranges). Under the unified scale, chemical shifts can thus be reported to a precision that is often dependent on linewidth or other sample-related factors, rather than instrumental factors. Since literature data for a number

of nuclides are usually referred to a secondary reference and hence are often of considerably lower precision, small discrepancies in values of $\mathcal{E}$ are of little practical consequence in most instances.

3.6 Practical Application of the Unified Scale

Modern NMR spectrometers invariably include field/frequency locking and frequency synthesizers, so that all frequencies are reliably interrelated by locking to a master clock frequency. There are two ways in which this fact can be used to determine chemical shifts, either directly on the $\mathcal{E}$ scale or with respect to a recognized reference for the nucleus in question. These two ways are equivalent to the use of the conventional internal reference and substitution methods, respectively. In the former case, if a nucleus X is to be studied, and the sample can be prepared with a small amount of TMS, then two direct frequency measurements made whilst maintaining the same ^2H locking conditions will provide the chemical shift of X on the unified scale according to equation 9. If this procedure is applied to a series of samples, the effect is to replace ‘medium effects’ on the shielding of X (given by measurements using a reference compound containing the nuclide X) by ‘medium effects’ on the shielding of ^1H in TMS. In general, this should result in a reduction of ‘medium effects’ due to the referencing procedure, which is desirable. Clearly, the substitution method can be used similarly and is particularly valuable when it is not convenient to add TMS to the sample. Equation (9) is still pertinent. However, as noted in Section 3.4, medium effects may vary to some extent if different concentrations of sample and reference are used.

In the future, reporting of chemical shift data as $\mathcal{E}$ values may become more common and acceptable. Conversion of $\mathcal{E}$ values to conventional chemical shifts relative to a reference of an X-containing compound requires only subtraction of the $\mathcal{E}$ value of a suitable homonuclear reference, as given in Tables 1 and 2, followed by division by the $\mathcal{E}$ value of the homonuclear reference. Thus:

$$\delta_{\text{X}}/\text{ppm} = 10^6(\mathcal{E}_{\text{X, sample}} - \mathcal{E}_{\text{X, reference}})/\mathcal{E}_{\text{X, reference}} \quad (10)$$

The widespread use of a ^2H lock for NMR measurements on isotropic samples suggests a modification of the substitution approach, since the relevant reference frequency should not vary with time. Thus the chemical shifts of the X nuclei can, in principle, be determined on the unified (TMS-based) scale merely by measuring the resonance frequency of the sample and using a predetermined reference frequency for the nuclide in question. Thus only one (sample) tube is required and no reference substance needs to be added. The predetermined reference frequency is obtained by measuring the proton resonance of TMS under similar conditions to the sample (i.e., with the same lock compound) in a single experiment for the spectrometer being used. Then the frequency of the usual secondary reference for the X nucleus can be calculated using the pre-determined value of ν_{TMS} :

$$\nu_{\text{reference}} = \nu_{\text{TMS}} \times \mathcal{E}_{\text{reference}}/100\% \quad (11)$$

where $\mathcal{E}_{\text{reference}}$ takes the appropriate value given in Tables 1–3. Thence the chemical shift (or the value of $\mathcal{E}_{\text{X}}$) for the sample can be readily derived. If the lock substance in

the sample solution is not the same as that of the reference solution, a lock correction must be applied (equation (8)).

As an example, suppose that a ^{77}Se resonance has been measured on a compound dissolved in acetone- d_6 , resulting in a value:

$$\nu_{\text{sample}} = 76\,344\,378 \text{ Hz}$$

On this spectrometer, the ^1H resonance of a $\varphi = 1\%$ solution of TMS in CDCl_3 has been found at 400 103 342 Hz when the spectrometer was installed. The reference frequency of selenium is then, from Table 1:

$$400\,103\,342 \text{ Hz} \times 19.071\,513 \div 100 = 76\,305\,761 \text{ Hz}$$

The proton chemical shifts of the resonances of the lock compounds are:

$$\delta_{\text{H}}(\text{CHCl}_3) = 7.27 \text{ ppm and } \delta_{\text{H}}(\text{acetone}) = 2.17 \text{ ppm}$$

Then:

$$\begin{aligned} \delta_{\text{Se, sample}} &= (76\,344\,378 - 76\,305\,761)/76.305\,761 \\ &+ (2.17 - 7.27) = 501.0 \text{ ppm} \end{aligned}$$

Since this is still basically a substitution method, an error will arise if the ^2H frequency of the solvent has been influenced by the particular sample used. For many samples which consist of dilute solutions the error is small, and for many nuclei with large chemical shift ranges the error introduced in this way is probably smaller than would occur if a homonuclear (X) reference were used in the conventional manner.

Reporting of $\mathcal{E}_{\text{X}}$ and δ_{X} measurements in future heteronuclear magnetic resonance studies will ultimately lead to a large set of consistent data, provided that values of $\mathcal{E}_{\text{X, ref}}$ are established and used consistently in all future work. Therefore, particularly for comparison with chemical shifts reported relative to a homonuclear (X) reference via conventional internal referencing procedures, it is essential that the values of $\mathcal{E}$ in Tables 1 and 2 represent the accepted values for the substances listed (which are the ‘best’ available at the present time). *We therefore recommend that the defined local chemical shift scale zero values are established as those listed in Tables 1 and 2, and that such definitions are not subject to future change arising from remeasurement even where this results in increasing accuracy for the reference compound in question.* However, the values of $\mathcal{E}$ for ‘rare earth’ nuclei in Table 3 should be regarded as provisional, pending more accurate measurement.

The Unified Scale offers many advantages over other methods of referencing. However, serious errors can occur in reading and displaying frequencies in some spectrometers unless care is taken. The software in NMR spectrometers is continually evolving, and even some spectrometers of relatively recent vintage are configured to display frequencies that are rounded off or that appear with many digits that do not correctly represent the frequency of a peak indicated by the cursor. The correct information is available in the appropriate parameter tables, but the authors of this document have found that in instruments which are several years old it may be necessary to seek the correct file and not rely on what appears to be an ‘obvious’ display. Although the situation has improved with the latest version of commercial instruments,

we strongly recommend that each user verify that his/her own instrument correctly determines one or more values of $\mathcal{E}$ as given in Tables 1–3.

3.7 Alternative Reference Compounds

Many of the elements have more than one proposed reference compound for the chemical shift scale mentioned in the literature. The majority are secondary reference standards chosen for convenience. Although our recommendation stands for the compounds listed in Tables 1 and 2, there are some situations where an alternative reference has to be used. One of these cases occurs when ^1H , ^{13}C , ^{15}N , ^{29}Si and other nuclei have to be referenced in highly polar solvents such as water, where TMS is only very sparingly soluble. For those situations, DSS or its partially deuterated form, $\text{Me}_3\text{SiCD}_2\text{CD}_2\text{CD}_2\text{SO}_3\text{Na}$, is the recommended primary reference.^{53,57} [Sodium 3-(trimethylsilyl)propanoate (TSP) is another salt that has been suggested.⁵⁸] When DSS is used as a reference, it has been recommended⁴ that ^1H chemical shifts be denoted by the symbol δ_{DSS} to distinguish them from those referenced to TMS. However, the resonances of DSS and TMS, *both dissolved in the same solvent*, are very close: On the scale with TMS as zero, DSS has a chemical shift of $\delta = 0.0173 \text{ ppm}$ in dilute aqueous solution, while in dilute solution in $\text{di}[(^2\text{H}_3)\text{methyl}] \text{ sulfoxide (DMSO-} \text{d}_6 \text{)}$, the chemical shift of DSS is $\delta = -0.0246 \text{ ppm}$ ⁴. For most purposes these differences are negligible (falling well below the anticipated range of solvent effects), and *data from the TMS and DSS scales may be validly compared without correction for the different ^1H reference.*

Table 4 repeats the recommended values of $\mathcal{E}$ from Reference⁴ along with data for additional references proposed in the literature for nitrogen, and compares them with our recommendations in Tables 1 and 2. For ^{13}C studies in aqueous solution, Reference⁴ recommends using the ^{13}C methyl resonance of DSS, rather than that of TMS, as the secondary reference. Carbon-13 chemical shifts based on DSS and TMS differ by about 2 ppm, which can cause confusion if not clarified. *We recommend that when ^{13}C chemical shifts are referenced to DSS, that point should be made clear by using a notation such as $\delta_{\text{DSS}}(^{13}\text{C})$.*

Reference⁴ recommends use of trimethyl phosphate (internal) as a secondary reference for ^{31}P studies in aqueous solution, whereas Table 1 recommends 85% phosphoric acid (external), which has been used more widely, particularly for chemical systems where use of an internal reference is not feasible. The two secondary references differ by about 3 ppm, so *it is important to specify which is being used.*

Several reference compounds have been used historically for nitrogen NMR, partly resulting from the very different properties and natural abundances of the two nuclides (^{14}N and ^{15}N). Nitromethane as either an internal or external reference has been the most widely used for ^{14}N and to some extent for ^{15}N , while liquid ammonia has been a popular external reference for ^{15}N . Ammonium and tetramethylammonium salts have been used as internal references for both ^{14}N and ^{15}N . Reference⁴ recommends liquid NH_3 as a secondary reference for ^{15}N in aqueous solutions, since most biochemical applications of ^{15}N NMR have used this reference. In Tables 1 and 2 *we recommend nitromethane as a reference*, in line with common usage in many other applications. The values of $\mathcal{E}$

Table 4 Alternative Secondary References

Isotope	Alternative secondary references				Recommended Secondary references ^a		
	Reference compound	Sample conditions	Frequency ratio	Literature $\pm$ 1%	Reference compound	Sample conditions	Frequency ratio
¹ H	DSS	Internal	100.000 000	4	TMS	Internal ^b	100.000 000
² H	DSS	Internal	15.350 608	4	TMS	Internal ^b	15.350 609
¹³ C	DSS	Internal	25.144 953	4	TMS	Internal ^b	25.145 020
³¹ P	(CH ₃ O) ₃ PO	Internal	40.480 864	4	H ₃ PO ₄ (85%)	External	40.480 742
¹⁵ N	NH ₃ (liquid)	External	10.132 912	4	CH ₃ NO ₂	External	10.136 767
¹⁵ N	[(CH ₃) ₄ N]I	Internal ^c	10.133 356	59,60			
¹⁴ N	[(CH ₃) ₄ N]I	Internal ^c	7.223 885	59	CH ₃ NO ₂	External	7.226 317

^aSee Tables 1 and 2.^bVolume fraction $\varphi = 1\%$ in CDCl₃.^c0.075 M in DMSO-d₆.

for different nitrogen reference compounds are presented in Table 4, along with those for tetramethylammonium iodide, which has been suggested as an internal reference for both ¹⁴N and ¹⁵N since the tetrahedral geometry results in sharp lines for both isotopomers.

For most of the nuclei listed in Tables 1 and 2, $\mathcal{E}$ values are listed for only one homonuclear reference, since conversions to other reference compounds can be readily made from literature values.

3.8 Magic-angle Spinning

It has been shown^{61–63} that in theory bulk isotropic magnetic susceptibility effects are eliminated by spinning an infinitely-long cylindrical sample with its axis at the magic angle (54.7°) to the static magnetic field of an NMR spectrometer. Therefore, in principle, magic-angle spinning (MAS) can be used in the external referencing method to obtain chemical shifts free from bulk susceptibility problems. Whereas this technique was proposed in the context of solid-state NMR (see below), its utility applies equally well to the solution state.^{64,65} In practice an infinitely long cylinder is not necessary to reduce bulk susceptibility effects on chemical shifts to an acceptable level. Strictly speaking, to correct for *isotropic* bulk magnetic susceptibility effects, it is also not necessary to spin at the magic angle, but merely to orient the cylinder containing the sample at the magic angle (see equation (7)). However, spinning may narrow the lines significantly and so is normally essential for accurate chemical shift measurement.

3.9 Solids

Sample-handling procedures differ substantially for solids from those appropriate for solutions, and there are clear advantages to using suitable solids as secondary references. This is almost always done using sample replacement. However, the spectrometers are generally used without field/frequency locking, so that the resulting chemical shifts are inevitably less accurate than those for solutions. This is not a significant problem, because linewidths are usually substantially greater than those for solutions and they impose an upper limit to accuracy. High-resolution NMR of solids almost invariably relies on magic-angle spinning, and, as discussed in Section 3.8, this eliminates the effects of differences in bulk isotropic magnetic susceptibilities. Early papers^{61,62} addressed this matter,

and a recent review by VanderHart,⁴⁵ which refers to both liquids and solutions, further discusses the influence of MAS for referencing spectra. Unfortunately, the situation is simple only for systems with isotropic magnetic susceptibility. VanderHart⁴⁵ discusses the case of anisotropic susceptibility, but there has been to date little experimental work in this area. However, in general it may be taken that, within the accuracy of measurement, referencing by sample replacement under MAS conditions in an unlocked but stable spectrometer is to a good approximation equivalent to the substitution method as described in Section 3.5.

Several papers^{66–68} take advantage of the MAS technique to suggest secondary solid standards for practical use in solid-state NMR. For example the ¹³C signals of solid adamantane, glycine, hexamethylbenzene and [(CH₃)₃Si]₄Si have been referenced to those for liquids and solutions using MAS, and data were reported to accuracies in the region of 0.004–0.04 ppm.

Chemical shift referencing for solid-state NMR is not yet at the stage where much further discussion is warranted here, so the only recommendation that we make is for referencing procedures to be always clearly and carefully stated in publications.

4 SUMMARY OF RECOMMENDATIONS

In addition to the endorsements of earlier Recommendations stated in Section 3.2 above, IUPAC recommends the following:

- Equation (5) should be used to define chemical shift scales, with symbol δ and with ppm (or ppb or %, as appropriate) explicitly stated after the numerical values. Equation (6) provides a simple way to calculate chemical shift values in ppm.
- The ¹H signal of tetramethylsilane in dilute solution (ca. volume fraction $\varphi = 1\%$ in CDCl₃) should be used as the primary *internal* or substitution reference for the resonance frequencies (and hence chemical shifts) for *all* nuclei. However, for aqueous solutions the recommendations of Ref.⁴ are supported.
- The secondary references listed in Tables 1 and 2 may be used for the nuclei of the various elements, with their $\mathcal{E}$ taking the fixed values given (not subject to revision).
- Internal referencing may be used for solutions but its limitations should be recognized.

- (e) For solution-state measurements, referencing via an internal ^2H lock signal may be used, either to give the value of $\mathcal{E}$ directly or to calculate the chemical shift with respect to the relevant secondary reference (via equation (8) where relevant).
- (f) Referencing by the substitution method with field/frequency lock spectrometers may also be used for solutions.
- (g) External referencing for either liquids or solids may be carried out with magic-angle spinning.
- (h) External referencing by means other than (f) and (g) is to be discouraged unless corrections are applied for bulk magnetic susceptibility effects.
- (i) In all circumstances, and especially where strict adherence to these Recommendations is not feasible, details of experimental procedures should be given clearly so that results may be validly intercompared.

Acknowledgements

We thank H. J. C. Yeh (National Institutes of Health), A. M. Kenwright (University of Durham) and B. Ancian (Université de Paris VII) for measurements of $\mathcal{E}$ for ^{13}C and ^{29}Si in solutions of TMS in CDCl_3 . Other special measurements of $\mathcal{E}$ have also been made by C. Brevard, R. Hoffman, J. Raya, M. Bourdonneau, T. Meersmann, B. Ancian and L. Helm. We are also grateful to W. Bremser, who participated in some of the early discussions on the topic of these recommendations, and to J. Kowalewski and G. Martin for comments and encouragement. Specific comments were received from members of IDCNS (W. V. Metanowski, K. Hatada, A. D. Jenkins, J. W. Lorimer, W. H. Powell, S. E. Schwartz, A. J. Thor, H. A. Favre, T. Cvitaš) and a wide range of NMR experts and others (A. D. McNaught, D. L. Van der Hart, D. T. Burns, M. Duteil, J. R. Everett, B. E. Mann, W. McFarlane, P. S. Pregosin, B. Mandava, W. von Philipsborn, T. D. W. Claridge, C. Ye, D. Neuhaus, P. Jonsen, G. Hägele, J. C. Lindon, P. E. Meadows, B. Wrackmeyer, D. L. VanderHart, K. Mizuno, T. Richert); we are very grateful for their assistance and guidance. P. Pyykko very helpfully supplied details of his review of quadrupole moments in advance of publication, and R. Hoffman not only supplied data for $\mathcal{E}$ on several nuclei but also made many pertinent and useful suggestions.

5 APPENDIX

As noted in the body of this document, a number of new experimental measurements have been made to verify values of $\mathcal{E}$ for various nuclides. Experimental details are given here.

Concentration dependence of δ_{H} (TMS).¹² Measurements were made with a Varian VXR-500S spectrometer, sample at ambient probe temperature (about 23 °C), locked onto the signal for CDCl_3 . Measured ^1H frequencies were as follows:

$$\varphi = 0.01\% : 499.872\,5048 \text{ MHz}$$

$$\varphi = 1\% : 499.872\,5054 \text{ MHz}$$

$$\varphi = 80\% : 499.872\,5495 \text{ MHz}$$

$\mathcal{E}$ for ^{13}C and ^{29}Si . Three measurements were made of $\mathcal{E}$ (^{13}C) for TMS in CDCl_3 at $\varphi = 1\%$, all at ambient probe temperature using the following spectrometers: – Varian VXR-500S,¹² $\mathcal{E} = 25.145\,0188\%$; Varian Unity-300,¹³ $\mathcal{E} = 25.145\,0202\%$; and Varian Inova-500,¹³ $\mathcal{E} = 25.145\,0196\%$. The reported value¹⁵ (Table 1) of $\mathcal{E}$ (^{29}Si) for TMS in CDCl_3

at $\varphi = 1\%$ was obtained at ambient probe temperature using a Bruker Avance-400 spectrometer.

Other values of $\mathcal{E}$. Most of the remaining 67 new measurements presented in Tables 1 and 2 were made by the substitution method (as described above) with a Bruker Model MSL spectrometer, operating at a nominal frequency of 300 MHz for ^1H , and with corrections applied for the lock signals (see equation 8).⁹ However, $\mathcal{E}$ was measured for the following nuclei using a Bruker Avance-400 spectrometer: ^2H , ^{17}O , ^{45}Sc , ^{47}Ti , ^{49}Ti , ^{55}Mn , ^{75}As , ^{81}Br , ^{87}Rb , ^{127}I , ^{131}Xe , ^{133}Cs , ^{135}Ba , and ^{137}Ba . The ^{21}Ne value was measured⁹ using a Chemagnetics Infinity 600 spectrometer. All 67 measurements were made at ambient probe temperature, approximately 298–300 K. The replacement reference samples used were either a concentrated solution ($m = 4.75 \text{ mol kg}^{-1}$, $\varphi = 80\%$) of TMS in CDCl_3 , or a $\varphi = 1\%$ solution of TMS in CDCl_3 . In the former case, the values have been converted to refer to TMS ($\varphi = 1\%$) in CDCl_3 (see above).

6 RELATED ARTICLE IN THIS VOLUME

Parameters and Symbols for Use in Nuclear Magnetic Resonance (IUPAC Recommendations 1997). The reader should note that together these two articles in this volume, Nuclear Spin Properties and Conventions for Chemical Shifts (IUPAC Recommendations 2001) and Parameters and Symbols for Use in Nuclear Magnetic Resonance (IUPAC Recommendations 1997), essentially replace the article Nuclear Spin Properties and Notation in volume 5 of the Encyclopedia. In fact some of the numbers in the tables have been changed from that article by updating and because the primary standard has been rebased from 4.75 m in CDCl_3 to 1% in CDCl_3 .

1 INTRODUCTION

From the early days of NMR, the word probe (or probe-head) has been used to refer to the complete piece of equipment intimately associated with the sample (except the sample tube). For the simplest experiments, the probe consists of the mechanical structure required to hold the sample in the 'sweet spot' of the magnet, a coil surrounding the sample, a tuning capacitor, and an rf transmission line. However, most chemical problems of interest require control over the sample environment (temperature, electromagnetic irradiation, pressure, orientation, and re-orientation), and apparatus associated therewith becomes a part of the NMR probe.

The modern NMR probe is a complex piece of apparatus designed to accommodate all of the environmental requirements of the NMR experiment. The radiofrequency (rf) portion often includes (a) an rf 'observe' channel optimized for highest signal-to-noise-ratio (SNR, or S/N, also called sensitivity) at the X nucleus frequency, (b) a less efficient rf channel for heteronuclear decoupling (usually ^1H , except for indirect detection), and (c) another low-efficiency channel for magnetic field lock (usually ^2H). Variable temperature (VT) control is achieved with a resistive heater in a gas stream that flows over the sample. In high-resolution liquids probes, slow sample spinning (10–200 revolutions per second, Hz) about the B_0 axis to average out azimuthal inhomogeneity in B_0 is usually accomplished with a pneumatic system external to the probe, but high-speed sample spinning apparatus (200–26 000 Hz) for solids averaging techniques is an integral part of a solids probe.

One of the most demanding technical aspects of liquids probes is the requirement of extremely high B_0 field homogeneity (as high as several parts per billion), but sometimes it is advantageous to be able deliberately to spoil the field homogeneity over precise time periods by applying field gradients. When very high gradients and fast switching are required, as in diffusion measurements or solids microscopy magnetic resonance imaging (MRI), the gradient coils must be as small as possible and incorporated into the probe. However, for most

MRI work with samples larger than 40 mm, the gradient coils are external to the probe.

Another challenging technical requirement is often that of minimizing NMR background signals from construction materials that contain trace amounts of the nuclide of interest—particularly for highly sensitive proton (^1H) experiments. Other technical complications may stem from provisions for optical or microwave irradiation and operation at extreme temperatures.

Addressing the often conflicting requirements of high sensitivity, high resolution, large spectral bandwidth, low background signals, wide VT range, high-speed sample spinning, intense irradiation, and uniform field gradients requires careful attention to a number of problems in materials science, physics, electrical engineering, and mechanical engineering. The engineering effort often makes the price of a probe comparable to the price of a new sports car.

2 GENERAL CLASSES OF NMR PROBES

2.1 Liquids Probes

Approximately 80% of NMR experiments are performed on high-resolution liquids probes designed for samples in axially aligned glass tubes in superconducting magnets using saddle-shaped rf coils or slotted resonators for signal reception. They are often required to achieve a spectral resolution of several parts per billion on slowly spinning samples. A small fraction of their usage has been for in vivo experiments on small living animals or ex vivo or in vitro experiments on surgically removed tissues kept alive for short periods of time by perfusion with nutrients in saline solutions furnished by a flow system in the probe. Most multinuclear liquids probes have provided proton decoupling with multinuclear observe and deuterium lock, but recently many have been designed for inverse experiments (proton detection with X -nucleus decoupling). At present, high-resolution liquids probes are commercially available for experiments from -180°C to 380°C .

2.2 Gradient Probes

Pulsed field gradient (PFG) and microscopy MRI probes are usually similar to conventional liquids probes with the addition of gradient coils for one or three axes respectively. PFG probes are used for the measurement of diffusion coefficients, solvent suppression, or selection of specific coherences. Their usage has grown very rapidly in the past several years because of the time savings they provide in two-dimensional NMR. Microscopy in vivo probes may include surface coils for improved localized signal reception.

2.3 Solids Probes

The original (and simplest) probe for NMR of solid samples is the wideline probe, which is normally characterized as being able to generate 90° pulse lengths less than $3\mu\text{s}$ (spectral excitation bandwidths greater than 80 kHz) by withstanding

peak rf coil voltages in excess of 3 kV. Often they are double tuned (DT) to permit cross polarization (CP) with high-power decoupling for increased sensitivity and resolution. High-speed magic angle spinning (MAS) of the sample is added in the CP MAS probe for line narrowing of spin- $\frac{1}{2}$ nuclei, and dynamic angle spinning (DAS) and double rotation (DOR) may be provided for quadrupolar nuclei. When sufficiently large single crystals of the sample can be grown, high-resolution spectra and the chemical shift tensor can be obtained using a single crystal probe that includes a suitable goniometer and crystal orientation mechanism.

3 HISTORICAL PERSPECTIVE ON NMR PROBES

Through the late 1960s ‘NMR’ implied ‘proton NMR of liquids’ unless specifically stated otherwise, and multinuclear probes were unheard of. There was a rather widespread misconception that sensitivity increased linearly with coil inductance, even though the early classic treatments^{1,2} were sound. High-inductance solenoids (1–50 μ H, compared with 40–200 nH for modern probes) wound around the sample tube could be used for efficient reception in the transverse field of the electromagnet, but audio field-modulation coils were needed to shift the detection frequency above the $1/\nu$ noise region of the phase-sensitive video detector. The orthogonal Helmholtz transmit coils could be driven with low-power (milliwatt) oscillators for most continuous wave (CW) techniques, and the transmit/receive coils were carefully isolated using Faraday shields and tuning paddles. Since low-impedance preamplifiers with low noise figures were not available, it was best to include the first stage of the preamplifier in the probe and match it (usually 300–2000 Ω) directly to the receive coil.

Although many time domain pulsed NMR experiments were performed in the first two decades of NMR for relaxation studies, the explosion of NMR techniques awaited the application of Fourier transform (FT) by Richard Ernst in 1966 to the time domain data to obtain the complete frequency domain spectra in a single free induction decay (FID). The increase in sensitivity was comparable to the ratio of the total spectral width to the narrowest line in the spectrum—often two or three orders of magnitude.^{3,4} (See also *Fourier Transform Spectroscopy*.)

Field shimming (homogenizing) was extremely crude and tedious prior to Golay’s development of the theory and practice of orthogonal shim coils.⁵ With the advent of FT NMR came more incentive to obtain higher resolution because of its dramatic impact on sensitivity. Ultrahigh purity (99.9995%) copper receive coils with precision magnetic compensation and Varian’s sample spinner mounted on top of the probe quickly became standard. An external lock employing a sealed sample and separate coil (usually tuned to ^{19}F or ^2H) beside the sample coil was used to stabilize the field.⁶

The probe rf circuitry was also quickly impacted by FT NMR. To excite the entire spectral width with large Helmholtz coils at 60 MHz required 10–100 W and generated several kV across the coil, so impedance matching to the transmit circuit became important. The increase in sensitivity from FT NMR opened up the field of multinuclear MR—especially ^{13}C and ^{31}P .⁷ The advantages in resolution and sensitivity provided by proton decoupling required double resonance circuits, which

made it more difficult to use separate transmit/receive coils, and double-tuned single-coil circuits with transmit/receive duplexers began to appear.^{8,9} It is fair to say that modern NMR probe technology was ushered in by David Hoult in 1976 with his transparent analysis of S/N based on the obscure concept of reciprocity.¹⁰ Today, separate transmit/receive coils survive only in single resonance MRI where the high rf homogeneity afforded by a large transmit coil is beneficial and small surface coils are optimum for reception.

Probe technology has matured over the past two decades, and major advances in most probe specifications are not expected. Nonetheless, probe technology will retain its pivotal role in NMR progress because even small improvements can contribute a lot to total system performance.

4 RADIOFREQUENCY ENGINEERING—BASICS

Basic rf engineering has been treated in a number of elementary texts^{11,12} and introductory review articles,^{13,14} but the probe engineer also needs a working understanding of some of the more advanced concepts in electromagnetic field theory.^{15,16} NMR signal reception is different from (and simpler than) antenna theory, in that antennas are designed to receive electromagnetic waves in the far-field limit whereas NMR probes are designed to sense magnetic fields in the near-field limit.¹⁷ While the rf circuits in NMR probes can usually be approximated with simple circuits and analyses, the critical importance of the probe to the total spectrometer performance justifies a level of detailed field and efficiency analysis seldom encountered outside of NMR probes. A number of articles^{10,18–25} and a textbook²⁶ have presented excellent treatments of general NMR probe design problems over the past two decades. A summary of basic NMR probe electronics follows.

4.1 Capacitance

Capacitance (farads) is defined as electric charge per volt (Q/V), and capacitive energy storage is equal to $CV^2/2$. Stray capacitance can often be estimated to sufficient accuracy from the expression for the parallel plate capacitor C_p of area A (m^2), separation distance d (m), and dielectric constant k_d ,

$$C_p = \frac{k_d \epsilon_0 A}{d} \quad (1)$$

or from the expression for the low-frequency capacitance of a coaxial capacitor²¹ of length h , dielectric o.d. d_o , and dielectric i.d. d_i ,

$$C_c = \frac{2\pi k_d \epsilon_0 (h + d_o)}{\ln(d_o/d_i)} \quad (2)$$

where ϵ_0 is the permittivity of free space, 8.84 pF m^{-1} . Parallel capacitors add algebraically, ($C_T = C_1 + C_2 + \dots$), while series capacitors add reciprocally ($C_T^{-1} = C_1^{-1} + C_2^{-1} + \dots$).

4.2 Inductance

The simplest definition of inductance L (henrys) comes from Faraday’s law of induction—the induced voltage divided

by the rate of change in current di/dt . For inductance calculations, the most practical ‘definition’ follows from the energy equation

$$U = i_T^2 L / 2 \quad (3)$$

where U is the total energy in the magnetic field (the integral of $B^2/2\mu\mu_0$ over all space) and i_T is the current at the pair of terminals generating the magnetic field $\mathbf{B}$. [We follow popular usage of denoting the magnetic flux density or induction field $\mathbf{B}$ (T) as the ‘magnetic field’ and $\mathbf{H} = \mathbf{B}/\mu\mu_0$ as the field intensity (A m^{-1}) where μ is the relative permeability of the material.] For all NMR probes, μ is always unity. The permeability of free space μ_0 equals $4\pi \times 10^{-7} \text{ H m}^{-1}$.

The inductance of the finite, multiturn, single layer rf solenoid of Figure 1 with a constant pitch, an integral number of turns, and a high surface coverage is given in nH, for dimensions in mm, by the following expression:

$$L_S = \frac{4n^2 r^2 (1 - 0.2/n)}{h + 1.2r^{0.9}} \quad [\text{mixed}] \quad (4)$$

where n is the number of turns (Figure 1 has five turns), h is the overall axial length, and r is the effective inside

Figure 1 A five-turn solenoid

radius, which for round wire is approximately equal to the inside coil radius plus 20% of the wire radius. The last term in the numerator corrects for the fact that the helix makes the effective coil length a little less than the overall length. The above expression is correct to within several per cent for $h/r > 0.2$. For the loop-gap resonator^{27,28} (a single-turn solenoid, also called a split ring), the helix correction term is dropped, and the coefficient changes to 3.9 to correct for current concentrating at the ends of the ring. Higher order corrections for multiturn coils with low surface coverage can be added.

Lead (parasitic) inductance is usually best estimated by calculating the inductance of a loop-gap resonator having a length equal to the diameter of the lead wire and $r^2 = A_C/\pi$, where A_C is the area enclosed by the loop formed by the leads. Sometimes lead inductance is better estimated from the expression for the inductance L_C of a coaxial transmission line:

$$L_C = \frac{\mu_0 h}{2\pi} \ln \left(\frac{d_o}{d_i} \right) \quad (5)$$

Clearly from equation (5), series inductors add like resistors ($L_T = L_1 + L_2 + \dots$); likewise, parallel inductors add reciprocally ($L_T^{-1} = L_1^{-1} + L_2^{-1} + \dots$).

4.3 Single Resonance Circuits

4.3.1 Power

Figures 2 and 3 illustrate the basic RLC series and parallel circuits, respectively. The losses in the series RLC circuit of Figure 2 are best represented by the total effective series resistance R_s (from the coil, capacitor, leads, etc.). For the parallel circuit of Figure 3, the losses may be represented more conveniently by a total effective parallel resistor R_p . In both cases, the basic equations from ac circuits apply for rms power P and peak power P_p . (Power is assumed to be rms unless denoted otherwise.)

$$P = \frac{P_p}{2} = \frac{i_p^2 R_s}{2} = \frac{V_p^2}{2R_p} \quad (6)$$

Power ratios are often expressed in dB, $10 \log(P_2/P_1)$, and power is often expressed in dBm—defined as dB relative to a milliwatt:

$$\text{dBm} \equiv 10 \log(1000P) \quad (7)$$

In practice, peak-to-peak voltages ($2V_p$) are usually measured on an oscilloscope, and the measurements are significantly influenced by harmonic distortion, VSWR (Voltage

Figure 2 Series RLC circuit

Figure 3 Parallel RLC circuit

Standing Wave Ratio), loading, and oscilloscope bandwidth. Most conventional liquids probes are excited with 100 W pulses of 10–80 μ s at the observe frequency (usually the low frequency, LF) at duty cycles below 0.1% while they are driven with 10 W at the decouple frequency (usually ^1H , the high frequency, HF) at duty cycles below 50%. Solids probes typically see LF pulses of 200–400 W with duty cycles up to 1% while irradiating with HF power of 50–200 W at duty cycles below 30%. Whole body MRI probes are usually driven with 1–10 kW at duty cycles below 0.5%.

4.3.2 Resonance

Since charge (q) equals CV and $i = dq/dt$, a capacitor reaches a steady-state (monochromatic) reactance X_C (analogous to resistance, V/i) of $1/i\omega C$ after several RC time-constants, where i is the imaginary unit, $\sqrt{-1}$. Likewise, since $V = -L di/dt$, an inductor has reactance $X_L = i\omega L$ and time constant L/R . For the normal high- Q condition ($Q = \omega_0/\Delta\omega_{1/2}$), resonance occurs when the inductive reactance X_L plus the capacitive reactance X_C equals zero. (Often the phase is omitted for convenience, but it must be remembered that the voltage phase in the inductor leads by 90° while in the capacitor it lags by 90° relative to that in the resistor.) Hence,

$$\omega_0 = \frac{1}{\sqrt{LC}} \quad (8)$$

At resonance, the series impedance of the series RLC circuit is R_s (since $X_L + X_C = 0$) and the parallel impedance of the parallel RLC circuit is R_p [since $(X_L X_C)/(X_L + X_C) = \infty$]. The 3 dB width $\Delta\omega_{1/2}$ of the resonance defines the quality factor of the unloaded (and unmatched) RLC circuit, and the following relationships are readily derived:

$$R_p = QX_L \quad (9)$$

$$R_s = X_L/Q = R_p/Q^2 \quad (10)$$

4.3.3 Matching

Since X_L is typically 20–200 Ω , R_s is usually less than 1 Ω and R_p is greater than 2000 Ω . For efficient coupling to the transmitter and preamplifier, the resonant circuit, transmission lines, preamplifier, and transmitter must all be matched to approximately the same impedance, although mismatches of up to a factor of two are often unimportant. The international standard is 50 Ω (except in the television industry, where it is 75 Ω). Figures 4 and 5 illustrate the two basic methods of impedance matching: shunt inductor and series capacitor.

The inductive matching technique has the advantage of not requiring a second high-voltage capacitor, but the matching

Figure 4 Shunt inductive matching circuit

Figure 5 Series capacitive matching circuit

range is limited by the difficulty of adjusting very small inductors. The required shunt inductor (for $R_p \gg Z_0$) is

$$L_M = L_T \sqrt{Z_0/R_p} \quad (11)$$

where L_T is the total series inductance ($L_s + L_M + \text{leads}$) and Z_0 is the transmission line characteristic impedance—normally 50 Ω . The resonant frequency is calculated from L_T and C .

The capacitive matching circuit simplifies multinuclear (broadband) tuning requirements as high-voltage (HV) variable capacitors are readily available. The required match capacitance (again, for $R_p \gg Z_0$) has reactance X_{CM} given by

$$X_{CM} = \sqrt{R_p Z_0} \quad (12)$$

and rms current equal to that in the transmission line, $\sqrt{P/Z_0}$. In practice, some combination of capacitive and inductive matching is often used, and capacitive voltage division is often employed to reduce the demands on the matching variable capacitor.²⁹ Properly ‘pruned’ transmission lines can also be used to transform impedance (see *Probes for Special Purposes*).

5 SIGNAL-TO-NOISE RATIO AND B_1

5.1 Magnetization and the NMR Signal

The NMR voltage signal S from a sample with susceptibility χ , with nuclear spins precessing at angle ϕ in magnetic field B_0 at angular frequency ω , detected by a coil that generates a circularly polarized (rotating) transverse field $B_1(r)$, over the sample volume V_S for current i , may be shown from the principle of reciprocity^{10,26} to be

$$S = \frac{\chi B_0 \omega}{\mu_0 i} \int_S \sin \phi B_1(r) dV \quad (13)$$

Simply put, the receiver coil need only be analyzed as a B_1 transmitter. For a uniform B_1 generated by a current i ,

immediately following a 90° pulse,

$$S = \frac{\chi B_0 \omega B_1 V_S}{\mu_0 i} \quad (14)$$

The equilibrium magnetization M_0 is given by^{1,6}

$$M_0 = \frac{\chi B_0}{\mu_0} = \frac{n_s \gamma^2 \hbar^2 I_x (I_x + 1) B_0}{3 k_B T_S} \quad (15)$$

where n_s is the number of spins at resonance per unit volume, γ is the magnetogyric ratio, I_x is the spin quantum number, k_B is Boltzmann's constant, T_S is the sample temperature, and $\hbar = h/2\pi$, where h is Planck's constant.

5.2 Thermal Noise

The Johnson (thermal) rms noise N from a resistor R_E for filter bandwidth $\Delta\nu$ (not ν/Q) is^{1,2}

$$N = (4 R_E k_B T_R \Delta\nu)^{1/2} \quad (16)$$

where T_R is the temperature of the resistor. (For $R_E = 50 \Omega$, $N = -168 \text{ dBm Hz}^{-1/2}$.) The effective series resistance (X_L/Q) of the loaded circuit is best determined by measuring Q . Other noise sources (interference, triboelectric, spurious, shot, microphonic, preamplifier) can usually be made negligibly small with careful engineering.²³

5.3 B_1 in the Rotating Frame

A linearly polarized oscillating magnetic field $2B_1$ (as in a solenoid) may be decomposed into the sum of two oppositely rotating circularly polarized fields, each of magnitude B_1 . One of these components can be used to drive NMR precession within a bandwidth approximately equal to its magnitude (in Hz) if it is transverse to B_0 ; the other has no effect on NMR precession, as its frequency in the rotating frame is -2ω . From the Biot-Savart law,¹⁵ B_1 at the center of a solenoid is given by

$$B_1 = \frac{\mu_0 n i}{2h \sqrt{1 + 4(r/h)^2}} \quad (17)$$

Using equations (3), (6), and (10), it may be shown that $U = PQ/\omega$, and B_1 may be expressed as follows for the infinite solenoid:

$$B_1 = \left[\frac{\mu_0 P Q}{2\omega V_C} \right]^{1/2} \quad (18)$$

where V_C is the coil volume. [Adding the term $1 + 4(r/h)^2$ in the denominator inside the brackets of equation (18) improves the accuracy for typical solenoids.]

The unloaded Q_0 of the typical multiturn solenoid (well below self-resonance and with high surface coverage) is, in mixed units, approximately

$$Q_0 \approx 6\sqrt{hrf} \quad [\text{MHz}^{1/2} \text{ mm}^{-1}] \quad (19)$$

Saddle coils (commonly, but incorrectly, called Helmholtz coils;¹⁵ more properly they could be called Ginsberg³⁰ or Golay⁵ coils) and slotted resonators^{19,25} are better suited for liquids NMR in superconducting magnets, as they generate a transverse B_1 while allowing axial access. Moreover, their axial symmetry makes it easier to obtain high B_0 homogeneity. The coefficient in equation (19) is reduced to a value of 2 for saddle coils with medium surface coverage, as is necessary for orthogonal double resonance operation.

The loaded circuit quality factor Q_L will be lower than that of the coil because of losses in capacitors, shields, and sample. A convenient method of measuring Q_L is with a reflectance bridge, where the appropriate Δf value is measured at -7 dB return loss, which may be calibrated with a 21Ω or 119Ω load on a 50Ω line.²³ (Q_L is not lowered much by 'matching' to the preamplifier if its noise figure is less than $\sim 1 \text{ dB}$.)

For any coil, average B_1 in gauss over the usable volume may be expressed in mixed units by the following:

$$\langle B_1 \rangle = \beta \left[\frac{\eta_E P Q_L}{f V_C} \right]^{1/2} \quad [\text{mixed}] \quad (20)$$

where β is a dimensionless function of coil geometry, f is in MHz, V_C is in mL, and η_E is the rf efficiency—the fraction of the power delivered to the rf coil and sample.²¹ The rf efficiency η_E is usually greater than 0.9 for single resonance circuits at low fields, but it may be less than 0.2 for double resonance at high fields. In practice, it is always necessary to measure rather than calculate Q_L , which then includes the capacitor losses. The above equation is still valid if η_E is then defined as $1 - \eta_L$, where η_L is the fraction of the power dissipated in inductors not generating B_1 (leads and coils added for multiple resonances).

For special high-resolution applications of solenoidal rf coils, the optimum h/r value is 2, and $\beta \approx 2.4$. For very lossy samples, the optimum h/r is the largest permitted by space constraints, and $\beta = \sqrt{10}$ for the infinite solenoid. For MAS, the optimum h/r is 3, and $\beta = 2.1$ when the coil is at the magic angle. For saddle coils and slotted resonators, β ranges from 0.8 to 1.4, depending on surface coverage, subtended angle, and the ratio of height to diameter.

A magnetic filling factor η_f may be defined by

$$\eta_f = \frac{\int B_1^2 dV}{\mu_0 U} \quad (21)$$

where the integration is over the sample volume V_S . From equations (3), (10), (20), and (21) comes a very practical (and exact) definition of the filling factor:

$$\eta_f = \frac{\beta^2 V_S}{20 V_C} \quad (22)$$

5.4 S/N

From the above, the S/N from a single 90° pulse with an optimum filter [$1/(\pi \Delta\nu) = T_2$, the spin-spin relaxation time, and $\Delta\nu < \omega/2\pi Q_L$] can be written as follows:

$$\begin{aligned}
S/N &= \frac{S}{2N} \\
&= \left[\frac{\hbar^2 \sqrt{\pi \mu_0}}{12 k_B^{3/2}} \right] \left[\frac{n_s \gamma I_x (I_x + 1) \sqrt{T_2}}{T_S \sqrt{T_R}} \right] (\eta_E \eta_f Q_L V_S)^{1/2} \omega^{3/2}
\end{aligned} \quad (23)$$

The extra factor of 2 in the denominator arises because S is the initial peak signal voltage that decays with time-constant T_2 and N is the rms noise voltage. The product of the two bracketed terms is $1.65 \times 10^{-5} \text{ s}^{3/2} \text{ m}^{-3/2}$ for protons in water with $T_2 = 0.1 \text{ s}$ and $T_S = T_R = 300 \text{ K}$.

A useful simplification of equation (23) is the following for given NMR conditions (sample, γ , B_0 , T_S , T_2 , technique):

$$S/N \propto \frac{V_S}{\tau_{90} \sqrt{P}} \quad (24)$$

where τ_{90} is the mean 90° pulse width obtained over sample volume V_S with power P .

5.5 Minimizing Losses

For small samples, the Q_L is usually dominated by coil resistance. However, above 400 MHz it may be dominated by capacitor losses unless extreme care is taken in their selection, and it may be necessary to parallel a number of low-value capacitors for sufficiently low capacitor losses. For large, lossy samples, Q_L and T_R are dominated by sample losses. Dielectric losses from electric fields in the sample may be reduced by decreasing the coil inductance and increasing the capacitance.^{20,31} Usually, the only ways to reduce power P_S deposited by the inductive mechanism in a sample of uniform resistivity by a rotating B_1 are to maximize the B_1 homogeneity and to maximize the rms flux path length ξ for a given volume, but sometimes it is possible to use insulating films to suppress currents in the sample.³² The presence of skin, fat, and bones in MRI can make the estimate of P_S as much as an order of magnitude too large when using a worst-case tissue resistivity ρ_S of $1.2 \Omega \text{ m}$.

$$P_S \approx \frac{B_1^2 \omega^2 V_S^2}{16 \pi \rho_S \xi} \quad (25)$$

Equation (25) is equivalent to the low-frequency limit given by Carlson²⁴ for a sphere, but the inclusion of ξ improves loss predictions for nonspherical samples. The loaded Q_L may be estimated from the unloaded Q_0 and the sample Q_S :

$$Q_L = \frac{Q_0 Q_S}{(Q_0 + Q_S)} \quad (26)$$

For reasonably uniform, linear B_1 , Q_S is approximately

$$Q_S \approx \frac{32 \pi \rho_S \xi V_C}{\mu_0 \eta_E \beta^2 \omega V_S^2} \quad (27)$$

The numerical coefficient in equation (27) is increased to 64 for circular polarization.

The ratio Q_0/Q_L has frequently been used as a figure-of-merit for coils in MRI, but this does not properly consider the

dielectric losses nor the major effects of B_1 inhomogeneity in surface coils.³³ equation (24) provides a better figure-of-merit, but it still does not adequately evaluate homogeneity.

The ‘birdcage’ resonator of Edelstein et al. made quadrature coils practical for generating a single rotating B_1 .^{22,34} Liquids and solids NMR find few applications for quadrature rf coils, as coil losses usually dominate. However, in MRI, when inductive sample losses dominate, quadrature coils offer up to a 40% improvement in S/N. For an advanced treatment of the birdcage resonator, the reader is referred to the article by Tropp.³⁵ (See also *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*.)

A proper calculation of L , B_1 , and Q_0 requires a knowledge of the surface current distribution in the conductors—especially in single-turn resonators.²⁵ The so-called ‘proximity effect’ is ambiguous. A better method of determining current distribution in large conductors is to iterate on Biot–Savart integration, letting the currents move around in the conductors to a minimum inductance ($2U/i_T^2$) configuration. The current usually prefers to take the shorter paths (inside surface) and tends to concentrate near regions of high flux curvature (end edges) and high flux density (nearby shields). The normal component of the rf magnetic field always vanishes near the surface of conductors, and the current penetrates only to a depth given by the classical skin depth:

$$\delta = \left(\frac{2}{\omega \mu_0 \sigma} \right)^{1/2} \quad (28)$$

where σ is the electrical conductivity. For copper at 300 K, $\delta = 6.4 \mu\text{m}$ at 100 MHz. Nonuniform surface current density is responsible for Q_0 being lower by a factor of 3–8 than would occur for uniform surface current density. In some cases, Q_0 may be improved by the use of Litz wire (woven wire, using individually enameled strands as fine as 0.03 mm).

6 DOUBLE RESONANCE

Two saddle coils, rotated 90° about the B_0 axis provide a convenient method of doing double resonance NMR with good isolation. However, only the innermost coil can have the optimum filling factor, and sometimes it is beneficial to have the same spatial distribution of the two rf fields, B_1 and B_2 . Also, triple- or quadruple-resonance NMR experiments are often useful. Thus, it is often desirable to double-tune or triple-tune a single sample coil, although Anderson described in 1973 a clever method of using three orthogonal, single-tuned coils.³⁶

The number of modes in a resonant circuit will generally be equal to the number of unique inductors or capacitors, whichever is fewer. (Resonant transmission lines may count as either.) It is sometimes necessary to add additional inductors or capacitors (producing extraneous modes) to improve isolation or to achieve balance at the frequencies of interest, although this can complicate tuning.^{37,38} The most common double-tuned circuit, shown in Figure 6, has been analyzed by several authors.^{21,23,39} It has an HF parallel mode and an LF series mode. The efficiency at the HF is increased by decreasing L_S/L_H , where L_S is the sample coil inductance and L_H is the HF tuning coil inductance. On the other hand, efficiency

Figure 6 Double resonance circuit

at the LF is increased by increasing L_S/L_H . In principle, if the losses in L_H and the tuning capacitors can be made vanishingly small compared with sample losses, the efficiency can approach 100% at both frequencies.⁴⁰ Rise time, however, will be degraded (because the total Q_L must increase), but this is seldom significant for in vivo experiments. For 8-mm sample coils, efficiencies at HF and LF are typically 40% and 75% respectively (when Q_L includes capacitor losses, as in the referenced analyses). From equations (20) and (23), B_1 and S/N are degraded only as the square root of the efficiency.

7 CONSTRUCTION MATERIALS AND TECHNIQUES

Although B_0 homogeneity specifications sound frighteningly stringent, the capability of orthogonal shim systems is such that only in the immediate vicinity of the sample is magnetic susceptibility critical. Austenetic stainless steels (with SI volume susceptibility $\chi_V = \mu - 1 \approx 0.02$) can often be used for thin-walled Dewars surrounding the sample region and for Dewared transfer lines, although glass is preferred if space permits. It is, of course, desirable to minimize the amount of shimming effort required when the probe is changed, so low-susceptibility construction materials and thin sections are preferred. The magnetic susceptibilities of the components immediately above and below the sample region (in the B_z direction) are more significant, and axial and azimuthal symmetry are both important.^{41,42}

The common aluminum alloys⁴³ 6063-T6 (0.7% Mg, 0.4% Si, up to 0.3% Fe) and 6061-T6 (1% Mg, 0.6% Si, 0.3% Cu, 0.3% Cr, up to 0.7% Fe) are usually acceptable for thin shield cylinders and support structure since the iron is usually in a nonmagnetic phase (FeAl_3 or Fe_2Al_7),⁴⁴ but they often present acoustic ringing problems below 15 MHz.⁴⁵ Jewelry bronze [copper alloy C22600, 87.5% Cu, 12.5% Zn, 0.005% (max.) Fe] is usually a better choice for shields and support structure because of its lower magnetism, much higher acoustic absorption, good electrical conductivity, high strength, and excellent finishing and joining properties. Iron content is also rather carefully controlled in the more readily available phosphor-tin bronzes, such as C51000 [94.8% Cu, 5% Sn, 0.2% P, 0.1% Fe (max.)]. Aluminum, silicon, and zinc bronzes (or brasses) have to be checked carefully if they are to be used within $r_b/3$ of the sample, where r_b is the bore radius, as iron contents can exceed 0.5%. Copper-rich iron compounds are not stable, and the solubility of iron in copper at 200 °C is only 13 ppm,⁴⁴ thus copper alloys are likely to be ferromagnetic unless the iron is bound up in iron-poor compounds (such as FeAl_3 or FeSi_2), in which case it is still strongly paramagnetic ($\chi_V \sim 2$ for Fe_2O_3). For B_0 above 2.16 T, the ferromagnetic components saturate with a high-field χ_V of 2.16 T/ B_0 .

The critical importance of high-integrity ground connections throughout multiple resonance probes cannot be overemphasized, especially as the wavelength becomes comparable to or shorter than four times the maximum dimension of the electronics region. Welding, press-fits, and solder joints are preferred over silver-filled epoxy and silver paint.²³ The external shield cylinders are often anodized for an aesthetically pleasing finish that also helps eliminate variability in grounds. Figure 7 illustrates three typical NMR probes: a high-resolution liquids narrow bore probe, a CP MAS wide bore probe, and a single crystal probe with a goniometer.

Quartz is usually selected for coil forms in high-field magnets because of its lower dielectric loss, even though its magnetic, mechanical, and acoustic properties are inferior to those of Pyrex. Acoustic ringing in quartz, Macor, and ceramic capacitors may cause problems at frequencies up to 50 MHz. Zirconia has often been used in MAS probes for solids because of its superior mechanical properties.

One of the best engineering thermoplastics is polyether ketone (PEK) because of its low dielectric loss and excellent chemical, thermal, and dimensional stability at modest cost, but other insulating materials (Kel-f, Teflon, Macor, Vespel, zirconia) are often chosen for specific background or thermal considerations. Fiberglass reinforced composites are also widely used, but they must be cleaned well after machining to

Figure 7 Three typical NMR probes

remove traces of steel from the tools, and the glass fibers may produce aluminum and silicon background signals. Excellent epoxies are available for securing components and mounting coils—such as Epo-Tek 354, 360, and 377 from Epoxy Technology, Inc., Billerica, MA, USA. Several brands of Kelf and heat-shrink Teflon have sufficiently low hydrogenous content for critical proton applications, but experimentation and careful control are necessary.

8 THERMAL ENGINEERING

Linewidth and lineshape are often critically dependent on temperature control and stability.⁴⁶ Most commercial probes are intended to operate from -100°C to $+120^{\circ}\text{C}$, but special liquids probes are commercially available for operation from -170°C to $+380^{\circ}\text{C}$, and solids probes are available to cover the range 35–900 K. Temperatures are usually regulated by using a dc resistive heater (designed for minimal magnetic interaction) to heat a stream that is directed past the sample.

First-order heat-transfer calculations and simple power balance analysis are generally sufficient in the probe design. The heater power P_H required to increase the temperature of the gas by δT with specific heat C_p ($1000\text{ J kg}^{-1}\text{ K}^{-1}$ for N_2) and flow rate G (typically $1\text{--}2\text{ g s}^{-1}$ for MAS probes) is

$$P_H = GC_p\delta T \quad (29)$$

The gas temperature is usually measured with a copper–constantan thermocouple shortly before it reaches the sample, but optical sensors have also been used.⁴⁷ Platinum resistors (RTDs) are best in the range from 20–75 K and above 700 K, but in the intermediate range they are not as accurate as a thermocouple unless small magnetic-field-dependent corrections are made. They are often used to sense the heater temperature for protection in the event of inadvertent loss of gas flow. The control problems are more difficult than usually encountered elsewhere because of the requirement for precision temperature control of a stream of low specific heat that may encounter large fluctuations in flow rate. Standard PID (proportional-integral-derivative) control algorithms have been incorporated within the past several years by all manufacturers with vast improvements over the simple PI algorithms used previously. Dynamic control stability can be further improved by adding a power estimate that is a function of temperature and flow rate, and fuzzy logic may have advantages. Lead shot has occasionally been used for a thermal ballast because of its high volumetric specific heat and low Debye temperature (105 K).

Heat-transfer calculations are often limited to simple conduction calculations through thin sheets:

$$P_T = k_T A \delta T / d \quad (30)$$

where P_T is the thermal conduction power (W), k_T the thermal conductivity (W m^{-1}) of the material, A the area perpendicular to the direction of heat transfer, δT the temperature difference between the two surfaces, and d the thickness in the direction of heat transfer. The other common conduction problem is through a thick-walled tube with i.d. d_i , o.d. d_o , and length h :

$$P_T = \frac{2\pi k_T h \delta T}{\ln(d_o/d_i)} \quad (31)$$

The high Reynolds numbers (often greater than 10^5) that are seen in Dewared transfer lines result in a very high heat transfer through the bare glass or metal joints unless they are lined internally with plastic tubing, in which case the above equation can be used to estimate the losses.

The extreme temperatures that are often desired^{48–50} can make differential thermal expansion responsible for stresses that exceed the rupture limit of one of the components in the probe if not properly designed. However, most of the materials used in NMR probes have high strength. The exceptions, Macor and glasses, tolerate high compressive stresses. Hence, even these materials can often be used with plastics in properly designed situations even though their thermal expansions differ widely. Macor is the only commonly used material that is likely to rupture from internal steady-state thermal stresses, as its maximum thermal stress temperature ($T_T = S/b_T E$, where S is tensile strength, b_T thermal expansion coefficient, and E the Young's modulus of elasticity) and thermal conductivity are both very low.

9 GRADIENT NMR PROBES

By applying magnetic field gradients in three orthogonal directions ($\delta B_z/\delta x$, $\delta B_z/\delta y$, $\delta B_z/\delta z$), it is possible to use NMR to image macroscopic structures, and indeed this has made clinical magnetic resonance imaging (MRI) an important medical diagnostic technique.^{51,52} Obtaining spatial resolution below 1 mm on liquid-like samples requires gradients above the 10 m T m^{-1} available in most clinical MR machines. Higher gradients are easily obtained by reducing the size of the gradient coils or improving their efficiency. MR microscopy generally involves incorporating the gradient coils into wide-bore or narrow-bore probes along with small rf coils so that spatial resolution down to $10\text{ }\mu\text{m}$ can be obtained on liquid-like samples. Limited imaging experiments are also then possible on solid samples.⁵³

Single axis gradients ($\delta B_z/\delta z$) based on Maxwell pairs (sometimes called anti-Helmholtz coils) are much easier to implement in small spaces and are very useful for diffusion experiments using pulsed field gradients (PFG).⁵⁴ Similar probes (with lower gradient coefficients, to keep digital-to-analog convertor and amplifier drift requirements more manageable) have recently become very popular for gradient enhanced spectroscopy (GES), as the run time is often dramatically reduced for 2D NMR.

Rapid switching of large gradient coils requires high-power audio amplifiers (up to 500 kW). Hence, the switching efficiency η_s is very important:

$$\eta_s = \frac{\alpha^2 d_s^4 h_s}{\mu_0 L} \quad (32)$$

where α is the gradient coefficient ($\text{T A}^{-1}\text{ m}^{-1}$), d_s the sample diameter, h_s the sample length, and L the gradient coil inductance. (The gradient coefficient is sometimes called the 'efficiency', but the above dimensionless definition is more consistent with other efficiency definitions.) The 'fingerprint'

design of Schenck et al.⁵⁵ achieves much higher η_s values than earlier Golay coils, but new proprietary designs achieve even higher efficiency.

Image linearity has often been described in terms of field linearity—the relative difference between the gradient field and a linear field at the edge of the sample. A better definition of image linearity is rms local deviation of the gradient from its mean value throughout the sample volume. This has also been called differential linearity. It is sometimes desirable to use highly nonlinear local gradients (more than 40% local deviation) and image distortion correction software so that higher gradients can be achieved,⁵⁶ but local deviation below 10% is usually preferred.

When the gradients are switched, eddy currents are induced in the cold radiation shield of the magnet that have long decay times because of the ultralow resistivity of copper below 40 K. Active shielding of the gradients greatly reduces the external fields generated by the gradients and permits rapid pulse techniques without excessive cryogen boiling or high-order compensation techniques.^{57,58} Acoustic resonances in the gradient coils are then likely to limit gradient decay time, particularly at very high fields, but novel coil geometries are becoming available that greatly reduce this electromechanical or acoustic efficiency.

1 INTRODUCTION

By the late 1950s, all of the physics important to high-resolution solution NMR seemed to have been identified. The basic interactions of chemical shift and scalar or J couplings, as well as the dynamics leading to spin relaxation and chemical exchange, were understood—at least in principle. It seemed that all of the relevant terms in the Hamiltonian that applied to NMR in isotropic solutions were known. Advances in NMR theory focused on the details of dealing with complex spin systems and their manipulation by pulse trains, or how the spins reflected molecular dynamics, as exemplified in this Encyclopedia. This article deals with the recent recognition of an additional term in the solution NMR Hamiltonian, namely, that for nuclear–nuclear exchange coupling, and the dramatic effects it can have on solution NMR spectra. The purpose is to provide the reader with as intuitive and physical a picture of this purely quantum mechanical effect as possible. More rigorous treatments of the details of the underlying physics may be found in the references.

2 EXPERIMENTAL OBSERVATIONS

The discovery of nuclear–nuclear exchange couplings or quantum exchange couplings in solution NMR spectroscopy^{1–3} grew out of NMR studies of transition metal polyhydrides in the 1980s. Kubas at Los Alamos National Laboratory had discovered a class of transition metal complexes that bind H_2 as an intact ligand, rather than oxidatively adding the H_2 to the metal center.⁴ This prompted a great deal of activity among inorganic chemists in the synthesis of new hydride and dihydrogen complexes, as well as the reinvestigation of many previously known systems. At the time, the synthetic chemists also postulated that species such as H_3^+ might also be stabilized as ligands in transition metal complexes. Solution NMR spectroscopy of 1H was usually the structural method of choice in these investigations, and the classic signature of an H_2 complex became a measurable value for $^1J(^1H, ^2D)$ in the HD isotopomer, usually of the order of 20–35 Hz. It was widely assumed that a large value of $^1J(^1H, ^1H)$ would be found in any H_3 complex.

In the late 1980s, Heinekey at Yale and Chaudret at Toulouse independently^{5,6} made some somewhat startling observations

in the 1H NMR of several transition metal trihydrides. In these systems, the spectra indicated that $^1J(^1H, ^1H)$ could be over 200 Hz. Since the coupling in molecular H_2 itself is only 280 Hz as inferred from the NMR of HD, these large values for 1J were at first glance evidence for the putative H_3^+ complexes. However, it soon became clear that these systems were not to be explained so simply. During the next few years, Heinekey carried out a set of classic experiments that formed the basis on which it is now accepted that these splittings are exchange couplings.

One of the first indications that the observed splittings were not due to the usual Fermi-contact mediated scalar coupling mechanism was their extreme sensitivity to temperature. Early on, the apparent J couplings seemed to be field-dependent. However, careful experiments by Heinekey showed that this apparent B_0 dependence arose from slight variations in the probe temperature on different instruments. The splittings in fact did not depend upon field, but instead were hypersensitive to temperature. Many alternate models were considered for explaining these observations at the time. Some invoked chemical equilibria involving an unusual thermally accessible state that would have unprecedentedly large J couplings. Several tunneling-type mechanisms were also considered, but these seemed difficult to resolve with the observation of these splittings in fluid media at close to ambient temperatures. (For a review of previous experimental observations, other models eliminated, and pertinent references, see Zilm and Miller.⁷) Heinekey then carried out some very important experiments employing 2D substitution. The resulting pattern of isotope shifts and the isotopic variations on the apparent values of $^1J(^1H, ^1H)$ in the remaining protons ruled out any sensible model involving chemical equilibrium.² Unfortunately, the spectra of the partially deuterated isotopomers themselves did not provide convincing evidence for the involvement of tunneling. While no $^1J(^1H, ^2D)$ couplings were observed, this observation could be explained just as convincingly by self-decoupling due to the rapid 2D relaxation in concert with chemical exchange as by a tunneling mechanism. The key experiment to perform became clear. The NMR of a partially tritiated isotopomer would have none of the complications encountered with deuterium. Given the difficulties in handling radioactive samples, this experiment was more than difficult to perform. The results were well worth Heinekey's efforts: a coupling that started as over 500 Hz in a perprotio molecule was reduced to a $^1J(^1H, ^3T)$ of less than 30 Hz at the same temperature.¹ This was the first conclusive evidence obtained in favor of the exchange coupling mechanism for these large temperature dependent couplings. The initial report¹ of this result and a theoretical framework for quantitatively accounting for these couplings and their temperature dependence was soon published. Simultaneously with this report, Jones and Weitekamp⁸ also proposed an exchange coupling mechanism in these systems, which utilized symmetry arguments, but with no additional experimental data.

3 THEORY

Exchange interactions among electrons are familiar to any student of solid state physics or quantum chemistry. They are central to the quantum mechanical description of bonding in

molecules and the mechanism of phenomena such as high-temperature superconductivity. The appearance of $JI_1 \cdot I_2$ type couplings in ESR spectra of triplet biradicals is a well-known spectroscopic manifestation of the electron–electron exchange interaction. For nuclei, quantum mechanical exchange interactions are less familiar, and until recently they were not known to affect high-resolution magnetic resonance spectra in any manner. (For references on quantum exchange in solid ^3He and in related electronic structure problems, see Zilm and Miller.⁷) The best-known example of heavy particle quantum exchange is in solid ^3He . In this system, diffusion rates and other properties are known in large part to be determined by ^3He – ^3He exchange interactions. NMR spectra of tunneling methyl groups at low temperature also display features related to rotational tunnel splittings, but these have not usually been considered as manifestations of an exchange interaction per se. Given that quantum effects such as these have typically been considered as purely low-temperature phenomena, it is not surprising that quantum exchange involving nuclei has not until recently been recognized as having any role in solution NMR spectroscopy.

Any theory accounting for quantum exchange must consider the total wavefunctions for the nuclei being observed, spanning both spin and spatial coordinates. In this respect, quantum exchange is quite distinct from the other terms in the NMR Hamiltonian. A typical NMR interaction can usually be written as a product of a spin operator and an interaction constant or tensor, which is an expectation value of the rest of the system Hamiltonian over all coordinates except spin. In quantum exchange, however, the spin coordinate and the spatial coordinate are correlated, and such a separation is not possible. To illustrate this, we shall consider a simple two-spin system where the spins occupy chemically inequivalent sites.

3.1 Molecular Dynamics

To understand quantum exchange in the context of NMR spectroscopy, we must first consider the quantum mechanics governing the Cartesian displacements of the NMR active nuclei, i.e., their orbital wavefunctions, and then see how this is coupled to their spin coordinates, i.e., the spin functions. For a start, we shall consider a simple two-particle quantum mechanics problem that is often somewhat misunderstood. Although our treatment will be quite similar to a number of familiar problems in tunneling (see, e.g., Atkins⁹), we should like to emphasize now that quantum exchange does not in fact imply that tunneling motions occur. This point will be clarified in the following discussion.

The molecular systems in which quantum exchange has been observed by NMR all are of the form (1)

where the other ligands collectively denoted by L_3 are typically another hydride, a cyclopentadienyl, and a phosphine. Single crystal neutron diffraction studies³ indicate that the hydrides are typical terminal hydrides having a single bond to the central transition metal atom M. Although the M–H linkages are

significantly more ‘floppy’ than C–H bonds, these hydrides are basically localized at their binding sites. To a very good approximation, the potential well that each of these hydrides experiences can be approximated by the harmonic oscillator potential as depicted in Figure 1(a).

A complete quantum mechanical treatment of the pair of hydrides under consideration would involve a six-dimensional potential energy surface describing the energy of all configurations of the two hydrides as they are moved relative to each other and to the metal center. As long as the hydrides remain outside each other’s van der Waals radii, the potential experienced by either is still roughly harmonic. If the hydrides do not have any appreciable interaction with one another, the problem reduces to that of two uncoupled harmonic oscillators.⁷

As a simple model for this system, consider two hydrides bound to a surface, each in locally harmonic single particle potentials, (2) and (3).

If the interaction between the two protons is sufficiently weak, their displacements are approximately harmonic except for the symmetric displacement towards one another. In this instance, each hydride feels a repulsive force, which rises rapidly as they near one another. The hydrides are also attracted to the potential minimum at the other binding site. It is the displacement of the hydrides along this type of coordinate that we shall focus upon.

A good model potential for displacements along this exchange coordinate is a double well potential such as that in Figure 1(b). Movement along this coordinate exchanges the two hydrides between the two wells. The reaction coordinate is a two-particle potential, and is necessarily somewhat complicated. If the hydrides simply each moved along the y axis towards one another, there would be an essentially infinite barrier separating the two configurations. The model we want to consider instead takes the coordinate to be a minimum energy type of path along which exchange is possible. At the barrier the two particles must move out of each other’s way along a path that takes them out of the (y, z) plane.

It is worthwhile to note what is, and what is not, important in the choice of this potential energy curve. The double well model is only one approach to connecting the two different possible ground state configurations of the hydrides. Displacement on a periodic rotational coordinate would also produce the type of effects to be discussed.¹⁰ The required features are only that the potential has two wells representing two distinct configurations and that there be a finite barrier separating them.

Having reduced the two-particle problem to a single internal reaction coordinate in a double well makes the problem fairly simple. We shall only consider the vibrational ground state in this potential, since we know that the hydrides are basically bound fairly tightly to their binding sites. This places them in one of the two configurations representing the double well minima. Near the bottom of either well, the potential is close to harmonic, and a good approximate two-particle ground state

Figure 1 (a) Depiction of two harmonic potentials at two different sites, with vibrational ground state wavefunctions. This is a reasonable description of two largely uncoupled M–H vibrators in a transition metal hydride. The coordinates are the displacements of the individual hydrides. (b) A model two-particle potential describing the change in potential energy as the two hydrides in the two sites shown in (a) are exchanged between the two sites. The coordinate is the reaction coordinate along which the exchange takes place. The wavefunctions shown are two-particle wavefunctions for the two degenerate configurations

wavefunction would be a Gaussian centered in either of the two wells. We define $\psi(L)$ as the configuration where the protons 1 and 2 were at sites A and B, respectively. This configuration can be written as a product of one-particle wavefunctions, i.e., $A(1)B(2)$, where $A(1)$ and $B(2)$ are the Gaussians representing the one-particle ground state vibrational wavefunctions in the single particle potentials representing the two binding sites. The other side of the double well would then be represented by the two-particle wavefunction $\psi(R)=A(2)B(1)$ [see Figure 1(b)].

It is tempting to apply what we know about the quantum mechanics of a single particle in a double well directly to this two-particle problem, since the mathematical formulation is now the same at this point (see, e.g., Atkins⁹). Because the wells are a finite distance apart, the wavefunctions for the two ground state basis configurations we have chosen overlap each well. This produces an off-diagonal element in the matrix for the system Hamiltonian $\hat{\mathcal{H}}_L$ that includes the interaction of the particles with both wells and each other. To get the best possible description of the ground state within this restricted basis set, we must diagonalize this matrix. If

Figure 2 Model double well exchange potential showing the two lowest energy eigenfunctions ψ_+ and ψ_- . The energies of these two states are split by $2J$ symmetrically about the energy of the two degenerate localized basis states

the two sides of the double well have the same depth, the basis states are degenerate. No matter how small the off-diagonal term, the two basis set wavefunctions will be mixed. As every student of quantum mechanics knows, in the single particle case the symmetric and antisymmetric combinations of the two Gaussians are then good approximations to the proper wavefunctions. The eigenenergies of the two eigenstates $\psi_{\pm} = \frac{1}{2}[\psi(L) \pm \psi(R)]$ for the symmetrical potential are $E_{\pm} = \bar{E} \pm J$ (see Figure 2). $\bar{E}$ is the unperturbed energy of either of the degenerate configurations given by

$$\int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \quad (1)$$

and J is the value of the off-diagonal matrix element

$$\int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \quad (2)$$

In the case of a single particle in the double well, the energy difference $2J$ is a tunnel splitting. The wavefunctions indicate that the particle is equally likely to be in either well. This is interpreted to mean that the particle is ‘delocalized’ over both sides of the potential. If a localized state is prepared by a superposition of ψ_+ and ψ_- , it will evolve in time according to the usual rules of time-dependent quantum mechanics. The picture that emerges is one of the maximum in the probability density oscillating between the two wells at a frequency $2J/\hbar$. One usually describes the particle as coherently tunneling from one well to the other at this rate. On the other hand, when the two wells are of differing depths, the particle quickly becomes localized. As long as the difference in the energies of the two states $\psi(L)$ and $\psi(R)$ is larger than the off-diagonal term J , these remain good states to first order in the perturbation treatment.

The mapping of the two-particle case onto this reduced one-particle description contains some subtleties. If the two

sites are energetically the same, i.e. the one-particle potentials at the two binding sites are identical, the configurations $A(1)B(2)$ and $A(2)B(1)$ will clearly have the same energies. The degeneracy will again be lifted by any finite matrix element connecting the functions $A(1)B(2)$ and $A(2)B(1)$, and there will be two states separated by a tunnel splitting. In the molecules we are considering, however, the hydrides are chemically inequivalent. This means that the local one-particle potentials are different, if only slightly so on a cm^{-1} scale. However, this does not necessarily break the symmetry of the two-particle potential along the exchange coordinate. If the two particles are identical, the basis configurations $A(1)B(2)$ and $A(2)B(1)$ representing $\psi(L)$ and $\psi(R)$ will still have the same energies. Exchange of identical particles can then be described by a mirror-symmetric two-particle potential in the exchange coordinate. If the hydrides are not identical (e.g., a proton and a triton), this symmetry will be broken, since the two basis configurations will have different energies. The eigenstates will then be localized, and no tunneling will occur. In this case of two distinguishable particles, the two sites would have to be identical for the exchange potential to remain symmetric.

The appearance of a potential for particle exchange with mirror symmetry is then a prerequisite for exchange splittings to appear in the energy level diagram for this two-particle system. Many familiar systems have this type of symmetry, but not all can display quantum exchange. For example, consider the umbrella mode of ammonia, or the chair-to-chair inversion of cyclohexane. In the gas phase, both displacements can be described by mirror-symmetric double wells. Placing these molecules into a condensed phase, however, breaks this symmetry. When either molecule inverts, it moves from one region of space to another. The presence of an anisotropic solvent shell around each site gives the configurations distinct energies. This is not the case for the transition metal polyhydrides we are considering, or other systems such as rotating methyl groups. In the transition metal hydrides, the configuration before and after the exchange of two hydrides occupies the same region of space. Rotation of a methyl group by 120° likewise results in a new configuration that occupies the same space as before the rotation. These displacements are then always instantaneously described by mirror-symmetric potentials, and thus will have exchange-type splittings appearing in their energy level structure. It should be emphasized that whether particles are identical or not depends only on the nature of the particles and not on their location in the molecule or lattice. However, whether a molecular rearrangement that exchanges identical particles is a truly degenerate rearrangement energetically depends on the relation of the molecule to the lattice at the beginning and the end of the rearrangement.

The above treatment of the two-particle exchange problem as a single pseudoparticle in a double well is only partially correct. This is because the two-particle wavefunctions have additional constraints. One must remember that the spatial portion of a wavefunction describes the probability of a particle's location. When several particles are described by a single wavefunction, the probabilities can only be ascribed individually to particles that are distinguishable. For indistinguishable particles, the identity (e.g., particle number) is irrelevant.¹¹ The wavefunction for a pair of identical particles can then only give the probability of finding a particle

of that type at any position. It cannot tell us the probability for finding a particular particle there.

Our interpretation of $\psi_{\pm}$ in the one- and two-particle cases, then, is somewhat different. For the single particle in the double well, the equal probability amplitudes on the left and right sides is taken as an indication that the particle is 'delocalized' over both sides. This notion is reinforced by the time-dependent behavior of a single particle in this potential if the initial state is localized as just discussed. On the other hand, the two-particle wavefunctions $\psi_{\pm}$ do not imply delocalization of the two particles, or of the configuration. These functions now simply state that the system is most likely in a configuration with one particle on the left and one on the right, but the identity of the configuration is indeterminate. We may not ask about the location of individual particles, since they are identical, and as such their labels are simply irrelevant. Thus, we see in the two-particle case that the indeterminacy as to which particle is on the left or on the right has replaced the delocalization that arises in the one-particle problem.

This statistical interpretation of the two-particle wavefunctions requires that any relabeling of the particle identities must leave the probability densities unchanged. Thus, the wavefunction must be the same, or at most change sign, when the particle labels are permuted. In accord with the well-known symmetrization postulate, wavefunctions for identical bosons are symmetric or remain the same, while those for identical fermions are antisymmetric or change sign, under particle label exchange. With this in mind, we return to the problem of two particles in the double well. Consider the case where the particles are of zero spin and are therefore bosons. The function ψ_+ has the proper symmetry, while ψ_- does not. The ground state can then only exist as ψ_+ , since ψ_- is an unacceptable wavefunction. The consequence of this is that a 'localized' state cannot be constructed by combining ψ_+ and ψ_- . The picture we arrived at in the one-particle state of an initially localized state periodically moving between the two wells is then inappropriate. The system can only remain in the ground state ψ_+ . This is most easily interpreted as the system being localized in one of the two possible indistinguishable configurations.

3.2 Including the Spin Coordinate

When the spin functions are included in the two-particle problem, the symmetry of the total wavefunction including spin must be considered. One place to start is to write the individual spatial and spin functions as separate symmetrized sets. For a pair of spin- $\frac{1}{2}$ nuclei the symmetrized functions are the symmetric triplet functions T_0 , T_{-1} , T_{+1} , and the antisymmetric singlet spin function S_0 . The total wavefunction for identical fermions must be antisymmetric with respect to exchange, and therefore ψ_+S_0 , ψ_-T_0 , ψ_-T_{-1} , and ψ_-T_{+1} are the only acceptable combinations. Now that spin has been introduced, the system can have an energy of either $E + J$ or $E - J$, depending upon the spin state of the nuclei. Any additional small interaction of the magnetic field would not be expected to change the situation with respect to the energy associated with the orbital or lattice terms of the Hamiltonian. On the other hand, magnetic interactions will mix the singlet and triplet spin manifolds. Any spin flip that occurs must also make up any difference in lattice energy accompanying the transition. The appearance of the exchange energy in an

NMR transition is then a consequence of the correlation of the spin states with the orbital energies associated with the displacements of the NMR active nuclei.

In general, the above type of prescription for determining properly symmetrized total spin + spatial wavefunctions is cumbersome. The resulting functions can be recast in a more physical and convenient basis, which we call the site spin basis.¹¹ Rather than deriving the site spin basis, we shall develop it directly from some basic symmetry considerations. Let us start by considering a pair of protons in chemically equivalent sites that comprise an AX spin system. Normally we ignore the complications brought on by the coordinate or orbital part of the wavefunction, and simply write the spin eigenfunctions as $|+ +\rangle$, $|+ -\rangle$, $|- +\rangle$, and $|- -\rangle$, where the labels refer to m_S for particles 1 and 2 in that order. These two-particle product basis spin functions themselves, however, do not have the proper symmetry with respect to particle exchange, i.e., $|+ -\rangle \neq \pm |- +\rangle$. This at first sight seems perplexing, since every NMR spectroscopist knows that these wavefunctions are what are always used for an AX spin system. The answer is that in actuality the spin labels do not refer to the particle identities. Instead, the functions are of the form $|m_S(A), m_S(B)\rangle$, i.e., the labels are according to the site identity, not the particle numbers. The function $|+ -\rangle$ says the particle in site A is in the + state, and the particle in site B is in the - state. What the function does not tell us is which particle is in which site. Therefore, the spin functions labeled according to the m_S in each site are automatically symmetric with respect to particle exchange. To differentiate the product basis labeled according to sites, we shall write these kets as $|+ -'\rangle$.

In using this site labeling convention, we must also relabel our spin Hamiltonian.¹¹ For instance, the Zeeman plus chemical shift term in frequency units for two spins would be written as

$$\hat{\mathcal{H}}_{cs} = -\nu_A \hat{I}_{zA} - \nu_B \hat{I}_{zB} \quad (3)$$

The resonance frequencies and spin operators are thus identified with the molecular site instead of a particle number. In most instances, this is in fact how NMR problems are typically handled, even though one may have the impression that one is using particle labels instead of site labels.

The overall symmetry of the total site spin basis function $\psi_{\text{site}} = \psi_{\text{orbital}} \psi_{\text{spin}}$ is then determined solely by the symmetry of the orbital wavefunction. For this pair of spin- $\frac{1}{2}$ nuclei, ψ_{orbital} must always be the antisymmetric function ψ_- , since ψ_{spin} is always symmetric with this site labeling convention. The total wavefunction for the $|+ -'\rangle$ spin state is then $\frac{1}{\sqrt{2}}[A(1)B(2) - A(2)B(1)]|+ -'\rangle$ (the normalization is only approximate, since we have ignored the small overlap term). As a shorthand, these site spin basis functions will be written as $|m_S(A), m_S(B)\rangle$, dropping the prime notation to imply the inclusion of the orbital portion. Remember that the labeling of the spin portion is according to site A and B, not particle 1 and 2, in these functions with the $[\]$ notation. In order to calculate a spectrum, it is instructive first to explicitly calculate a few matrix elements. We shall use the sum of the coordinate Hamiltonian for the particles, $\hat{\mathcal{H}}_L$, and $\hat{\mathcal{H}}_{cs}$ as an example.

First consider $\langle + - | \hat{\mathcal{H}}_{cs} | + - \rangle$. Using the site labeling convention, this is evaluated as $\frac{1}{2}(\nu_B - \nu_A)$ in the usual fashion. The integral over the particle coordinates is unity, since the

orbital function is normalized. To calculate $\langle - | \hat{\mathcal{H}}_L | + - \rangle$, we must expand $|+ -\rangle$ in terms of functions with particle labels:

$$|+ -\rangle = \frac{1}{2}[A(1)B(2)|+ -\rangle - A(2)B(1)|+ -\rangle] \quad (4)$$

Since the spins have particle number designations on the right-hand side, the + and - labels have been arranged to keep the + spin in the A site and the - spin in the B site. The quantity $\langle + - | \hat{\mathcal{H}}_L | + - \rangle$ can be written as a sum of products of integrals over spin and space separately:

$$\begin{aligned} \langle + - | \hat{\mathcal{H}}_L | + - \rangle &= \frac{1}{2} \langle + - | + - \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad + \frac{1}{2} \langle - + | - + \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle - + | + - \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle + - | - + \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \end{aligned} \quad (5)$$

Note again that the spin labels on the left refer to sites A and B, while those on the right refer to particle numbers 1 and 2. The first two integrals each give $\frac{1}{2}E$, and the last two are zero because of the vanishing integral over the spin coordinate. The net value of the element $\langle + - | \hat{\mathcal{H}}_L | + - \rangle$ is then the lattice energy E . Now consider the element $\langle - + | \hat{\mathcal{H}}_L | + - \rangle$. In a similar fashion, the integral can be expanded as

$$\begin{aligned} \langle - + | \hat{\mathcal{H}}_L | + - \rangle &= \frac{1}{2} \langle - + | + - \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad + \frac{1}{2} \langle + - | - + \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle + - | + - \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle - + | - + \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \end{aligned} \quad (6)$$

In this case, the first two integrals are zero, and the second pair give contributions of $-\frac{1}{2}J$ for a total value of $-J$.

The reader may already see that these matrix elements can be evaluated on inspection following a few simple rules. When dealing with the NMR or spin Hamiltonian, we proceed as normally, using spin operators, interaction coefficients, and spin functions labeled according to site. The coordinate part seems trickier, but can be simply treated as a permutation operator over the spin. For a term $\langle ij | \hat{\mathcal{H}}_L | kl \rangle$, a value of E is returned if $i = k$ and $j = l$. If $i = l$ and $j = k$, a contribution of $-J$ is obtained. The additional terms that the exchange interaction brings to the NMR Hamiltonian can then be recognized as having the same form as the classical exchange matrix familiar to students of dynamic NMR lineshape analysis.

Table 1 Hamiltonian Matrix in the Site Spin Basis for a Simple AX Spin System

	$ + +\rangle$	$ + -\rangle$	$ - +\rangle$	$ - -\rangle$
$\langle ++ $	$-\frac{1}{2}\nu_A - \frac{1}{2}\nu_B + E - J$	0	0	0
$\langle +- $	0	$-\frac{1}{2}\nu_A + \frac{1}{2}\nu_B + E$	$-J$	0
$\langle -+ $	0	$-J$	$+\frac{1}{2}\nu_A - \frac{1}{2}\nu_B + E$	0
$\langle -- $	0	0	0	$+\frac{1}{2}\nu_A + \frac{1}{2}\nu_B + E - J$

For our simple AX spin system, the full Hamiltonian matrix in the site spin basis can then be written on inspection as in Table 1. Since the orbital energy E only adds to the diagonal, it just represents a shift of the energy scale and can arbitrarily be set to zero. If the chemical shift difference $|\nu_A - \nu_B| \gg |J|$ then the off-diagonal terms will be truncated, and the NMR transitions will give two doublets centered at ν_A and ν_B with splittings of $-2J$. This Hamiltonian then gives the same spectrum as that for an AX spin system with an effective J coupling of $-2J$. Since the matrix element that J represents is inherently negative, the apparent coupling in the spectrum is positive. For spin- $\frac{1}{2}$ nuclei, it can be shown that any pairwise exchange interaction gives rise to a term that behaves just as if there were a scalar coupling $-2J$ between those two sites. Higher-spin systems, however, cannot be described by such a simple effective spin Hamiltonian.¹¹

One could incorrectly infer from the energy level structure of this simple example that the identity of the particles can somehow be made known by the fact that they experience different chemical shifts at the two different sites. A question that might be asked is how often the spins can change places by tunneling. The answer turns out to be that one cannot tell. The probability that a spin in site A has exchanged with a spin in site B becomes a maximum when their spin quantum numbers are identical. In other words, the spins can tunnel when one cannot tell them apart, even by their spin. Therefore, the most straightforward interpretation is that the spins remain localized, but which spin is localized where is something that cannot be known, since the particles are indistinguishable.

The advantage of the site spin basis approach to treating exchange coupling in NMR spectroscopy is that it is very easily extended to more complicated permutations or exchanges of spins, and is easily applied to problems involving nuclei of arbitrarily large I . The general form of the exchange Hamiltonian in the site spin basis can be shown¹¹ to be

$$\hat{H}_{\text{ex}} = \sum_i \xi^{p(i)} J_i \hat{P}_i(k, l, m, \dots) \quad (7)$$

where $\xi = e^{2\pi i I}$ and I is the spin quantum number of the nucleus in question. The permutation of the spins among the sites $k, l, m, \dots$ is represented by the operator $\hat{P}_i(k, l, m, \dots)$, which acts on the spin labels within the site spin basis functions. Each site spin basis function has the same orbital function implied. For fermions, this is formed using a Slater determinant for the orbital states for each site. If the nuclei are bosons, an antideterminant is used instead. The exchange matrix element is given by J_i . It is calculated by taking the matrix element of $\hat{H}_L$ between an orbital state for one configuration and that of the configuration resulting from the permutation. For example, consider a three-site problem (e.g., a methyl group). A starting configuration would be

$A(1)B(2)C(3)$. If the three particles are subjected to a cyclic permutation, this state would become $A(3)B(1)C(2)$. The value of J_c would be

$$J_c = \iiint [A(1)B(2)C(3)]^* \hat{H}_L A(3)B(1)C(2) d\tau_1 d\tau_2 d\tau_3 \quad (8)$$

Different permutations have different parities. For bosons, this is irrelevant. However, for fermions, permutations of even parity produce negative elements, and those of odd parity give positive exchange integrals. This is handled by the $\xi^{p(i)}$ term. If the nuclei are fermions with spin $I = n + \frac{1}{2}$ then $\xi = -1$. If they are bosons then $\xi = +1$. For fermions, a single pairwise permutation has odd parity, and $p(i) = 1$, which produces a negative sign for the exchange matrix element. On the other hand, a permutation that can be written as the product of two pairwise permutations has even parity, and $p(i) = 2$. These permutations give positive exchange coupling elements in the Hamiltonian matrix. One can show by straightforward but tedious calculations that the results of this prescription are to reproduce the matrix elements that would be obtained by expanding the site spin basis functions as products of properly symmetrized orbital functions and spin functions with particle labels, and performing the integration explicitly.

In practice, one simply associates a different J value with each particular topological rearrangement or permutation of the nuclei between the different locations in a molecule. High barrier permutations give low J values, and facile permutations give larger ones. The states that are connected are those where the permutation operation shuffles the spin labels so that they match those of the state to which it is coupled. The procedure is exactly the same as filling an exchange matrix for a classical chemical exchange lineshape problem. The signs of the elements are determined by whether the spins are fermions or bosons, and whether the permutation has even or odd parity. These elements are added to the rest of the standard NMR Hamiltonian, and the spectrum is determined by finding the eigenstates and determining the transition moments in the usual fashion.

A convenient starting point for computer simulation of exchange-coupled spectra in the presence of chemical exchange is to start with any of the many programs for dynamic NMR lineshape simulation. One simply duplicates the code for calculating the elements of the classical exchange matrix, and uses it to add exchange coupling elements to the Hamiltonian matrix. In this manner, we have been able to computer-simulate exchange-coupled NMR spectra for systems of up to four chemically exchanging protons or deuterons.

3.3 Temperature Dependence

Our main purpose so far has been to provide a physical picture of how exchange interactions produce splittings in

NMR spectra. The theory accounts for the disappearance of exchange couplings between different isotopes of the same element, for the persistence at ambient temperatures of an effect that is similar to tunneling, and for the different spectral patterns that are observed for spin- $\frac{1}{2}$ and spin-1 systems (see below). Accounting for the size of these splittings and their temperature dependence is another matter. Several models have been proposed, and probably all are correct to some extent. A definitive calculation of the exchange coupling would require an accurate $3N$ -dimensional potential energy surface for N identical nuclei. This is at present out of reach, so the models are either approximate analytical or computational attempts to focus on key features of the exchange process.

The model we have favored most is based on a treatment of exchange in solid ^3He by Landesmann.^{2,7} Landesmann has analytically calculated the ground state exchange splitting for two atoms in harmonic wells and repelled by a hard sphere potential. To account for the temperature dependence, thermal excitations that place the molecules in higher vibrational states are involved. Since these vibrationally excited states are more delocalized, there is more overlap of the individual particles with the neighboring sites, and the size of J goes up with vibrational quantum number. In the double well description, the splittings of the higher states increase exponentially as one moves beyond the ground state. In solution, the vibrational states are short-lived, and the NMR experiment measures a Boltzmann population weighted average of the splittings over the vibrational ladder. The spin state is conserved in these transitions, and the sign of J remains the same; therefore, the weighted average of J increases with temperature. We have shown that the sum over vibrational states can be effectively accomplished by first calculating a Boltzmann population weighted overlap function.⁷ This can be shown to be approximated by a Gaussian of increasing width with increasing temperature. As Landesmann's ground state calculation used a Gaussian basis set, this result can then be applied to the averaged splitting as a function of temperature also. The final expression obtained is

$$J(T) = \frac{-3\hbar a}{8\pi m \delta(T)^3} \sqrt{\frac{3}{\pi}} \exp\left[-\frac{3}{4} \frac{a^2 + \lambda^2}{\delta(T)^2}\right] \quad (9a)$$

where

$$\delta(T)^2 = \frac{3h}{4\pi m \nu} \coth\left(\frac{h\nu}{2kT}\right) \quad (9b)$$

Here a is the inter-hydride equilibrium distance, λ is a hard sphere radius (usually taken as 10 nm), ν is the bending frequency of the M–H bonds, and m is the proton mass. When deuterium or tritium is involved, the mass and bending frequency are adjusted accordingly.

Equation (9a) can be used to fit J versus T data, and both a and ν determined. The values found in a large number of fits are quite close to the distances a found by single crystal neutron diffraction and the few ν bending frequencies that have been measured.² For systems with very large ^1H – ^1H exchange interactions, this equation has correctly predicted the size of the ^2D – ^2D exchange couplings when they can be measured. This equation also explains why exchange couplings are not observed in organic molecules. The exchange coupling decreases about two orders of magnitude for every 100 cm^{-1}

increase in ν . Since C–H bends are of the order of 600 cm^{-1} higher than M–H bends, the exchange couplings in organic systems are about 10^{12} smaller and thus unobservable.

Jones and Weitekamp have developed a similar model using numerical diagonalization of model double well potentials.¹² The behavior of J versus T is calculated by a sum over the thermally populated states. One difficulty with this approach is making a connection between the model reaction coordinate and the molecular structure. Harris and co-workers¹³ have studied exchange using muffin-tin-type potentials. They are also able to account for the observed data, and have offered some insight into the types of reaction coordinates that may play an important role.

Limbach¹⁰ has proposed an alternative model to these that is most different in the assumed exchange coordinate. This is a rotational model that produces an exchange splitting from a periodic exchange potential. In the rotational tunneling problem, the tunnel splittings alternate in sign with increasing rotational quantum number. One might then expect that the exchange coupling would have to decrease with temperature in this model instead of increasing as is observed. To circumvent this problem, Limbach proposes that in the ground state the hydrides have no appreciable rotational tunnel splitting. Thermal excitations then allow the system to access a state that is a nascent H_2 complex. The H_2 ligand in this state has a substantial tunnel splitting, which produces the appearance of the exchange coupling. The temperature dependence arises from the thermal population of essentially just the lowest rotational state of the H_2 complex. Such a model can also be used to fit all of the experimental data collected on perprotio systems to date. The main difficulty with this model is rationalizing the existence of an H_2 complex that must lie only $4\text{--}8\text{ kJ mol}^{-1}$ above the ground state trihydride structure. In addition, the barrier to rotation of the H_2 ligand in the thermally excited state must be well over 40 kJ mol^{-1} to properly account for the apparent tunnel splitting in the lowest rotational state of this nascent H_2 complex.

Differentiation of how well these and other models describe these systems is being tested by several computational groups at present.^{14,15} Potential energy surfaces are calculated for a model system, and the Hamiltonian is then numerically diagonalized. A Boltzmann population-weighted average over the calculated exchange splittings is computed for comparison to the experimentally observed variation of J with temperature. Such calculations can be made to reproduce the trends observed experimentally. However, it remains to be seen how high a level of calculation will be needed to do a better job than the approximate analytical theories.

4 EXAMPLES

A large number of transition metal hydride systems that display exchange couplings have been discovered or rediscovered. One of the most striking is the $\text{Cp}^*(\text{CO})\text{IrH}_3^+$ cation. At 500 MHz, spectra similar to the simulations shown in Figure 3 are observed.¹⁶ This is a deceptively simple AB_2 spectrum, which at first glance is a single line. On closer inspection, one sees that the central line is flanked by two broader lines with integrated intensities of approx. one-tenth of the central peak. This is an example of a dynamically broadened spectrum with a very large $J(^1\text{H}, ^1\text{H})$. The apparent

Figure 3 Simulated AB_2 dynamic 1H NMR spectra similar to what are observed at 500 MHz and about 140 K for the $Cp^*(CO)IrH_3^+$ cation.¹⁶ $J = -2J$ in these simulations is (a) 50 kHz, (b) 25 kHz, and (c) 18 kHz. The central line appears at the weighted average of the A and B chemical shifts. One of the dynamically broadened wings appears at the A-site chemical shift. In comparison with the experimental spectra, only simulations with $J = -2J > 50$ kHz produce a narrow enough central peak. In such cases where $|\nu_A - \nu_B| \ll J$, the central line does not broaden as the decoalescence temperature is reached—rather, only the outer wings narrow. This can lead to the impression that such a molecule is fluxional when in fact it is not

$J = -2J$ must be over 50 kHz as judged from comparison of these simulations with the experimental spectra. This large J lead us to predict that the exchange interaction in the perdeutero system would be of the order of 30–60 Hz and thus observable. Figure 4 shows an example of 2D – 2D exchange coupling observed in this molecule. Simulation of this spectrum requires an exchange coupling. This is because, for spin $I = 1$, the Hamiltonian no longer has the same symmetry as a scalar coupling; therefore, these data cannot be simulated using a scalar coupling network. From the dependence of J on T , one can extract the parameters a and ν , which predict that $J(^1H, ^1H)$ should be approx. 75 kHz, in accordance with the observed 1H spectra. In future, it will be important to find systems in which both the 1H and 2D exchange interactions can be accurately measured as a test of exchange coupling theories.

As a final example, Figure 5 displays some calculated 2D exchange-coupled spectra for AB_2 spin systems with various ratios of exchange coupling to the chemical shift difference. A D_B – D_B scalar coupling has also been included. Note that the scalar coupling between two magnetically equivalent nuclei is now seen to have an effect upon the spectrum! This result is expected, since the D_A – D_B exchange interactions do not commute with the D_B – D_B scalar coupling Hamiltonian, making it possible now to observe it in the spectra.

Figure 4 (a) Experimental 2D NMR spectrum of a mixture of deuterated isotopomers of the $Cp^*(CO)IrH_3^+$ cation (approx. 60% D) at about 145 K. (b) Simulated spectrum giving a D–D exchange coupling between the A and B sites of approx. 40 Hz. Such spectra cannot be fitted using a scalar coupling network

5 SUMMARY

Exchange couplings in solution NMR spectra are manifestations of a purely quantum mechanical effect on the energy levels of sets of identical nuclei in molecules. These effects are related to rotational tunnel splittings in systems such as H_2 or methyl groups, and have the same origins as quantum exchange in solid 3He . The unique feature of exchange coupling in transition metal polyhydride systems is that it persists to relatively high temperatures in the solution phase, making it possible to observe very small exchange splittings by

Figure 5 Calculated ^2D NMR spectra for an AB_2 spin system with scalar and exchange couplings (the chemical shift difference has been set at 400 Hz): (a) no couplings; (b) scalar couplings $J(\text{A}, \text{B}) = 30$ Hz, $J(\text{B}, \text{B}) = 0$; (c) scalar couplings $J(\text{A}, \text{B}) = 30$ Hz, $J(\text{B}, \text{B}) = 100$ Hz; (d) AB exchange coupling $|-2J| = 30$ Hz, scalar $J(\text{B}, \text{B}) = 0$; (e) AB exchange coupling $|-2J| = 30$ Hz, scalar $J(\text{B}, \text{B}) = 100$ Hz. Note that in (c) the inclusion of $J(\text{B}, \text{B}) = 100$ Hz has no visible effect, while the spectrum in (e) is dramatically different from that in (d) when $J(\text{B}, \text{B})$ is introduced

high-resolution NMR. While these splittings are related to tunnel splittings, they do not imply that coherent tunneling motions occur. Rather, they are a consequence of shifts in the orbital energies of the nuclei that are correlated with their spin states. This correlation of spatial and spin variables results in the exchange energy appearing in the transition frequencies observed in NMR spectra.

Acknowledgments

My work in this area has benefited from many interactions with NMR spectroscopists, inorganic chemists, and theoreticians interested in transition metal hydride chemistry. Especially important to me has been my close and very enjoyable collaboration with Professor D. Michael Heinekey and his group. Without his careful attention to experimental detail, the phenomenon of exchange coupling in solution NMR spectra would probably still remain undiscovered.

1 INTRODUCTION

The purpose of this review is to outline a few NMR concepts and relationships that carry over into the realm of quantum and laser optics. It is natural that the semiclassical physics of resonance excitation in two quantum level systems should be common to both quantum optics and NMR. Solutions of the Bloch–Maxwell equations serve as a model for analogs of NMR experiments that occur in quantum optics. The resemblances to NMR of effects in quantum optics cannot have a strict one-to-one relationship in every property, but they do exist in varying degrees. There is no intent here to present a comprehensive review of these analogs, but rather to focus upon principles of coherent macroscopic emission of dipole radiation. Although a number of NMR conditions and effects may be conceived in the domain of quantum optics, they are not always easy and routine to demonstrate, because the required experimental parameters in quantum optics are often more difficult to implement.

There are obvious differences between NMR and quantum optics. The effects of spontaneous emission and wave propagation are absent or negligible in NMR, but dominate in quantum optics. For this reason, there are numerous quantum optical effects that have no counterpart in NMR. Conversely, there are unique conditions and experiments in NMR that do not have analogs in quantum optical systems. For example, there is no simple direct optical analog of a NMR dipolar reservoir to be distinguished from the Zeeman reservoir. The validity of an optical electric ‘dipolar reservoir’ temperature in a coupled optical electronic two level system in the rotating frame of reference has not so far been demonstrated. In solids, strong exchange electric interactions of optical dipoles among themselves, or with the host lattice, prevent the distinction between an optical electric dipolar and a ‘two level internal splitting’ (analogous to Zeeman splitting) reservoir. In NMR, the weakly interacting nuclear moment permits the definition of isolated spin reservoirs to a high degree. Therefore, decoupling of spin–spin magnetic dipole–dipole interactions from externally controlled spin Zeeman interactions can be achieved over

long relaxation times. In quantum optics, short lifetimes of excited states are associated with strongly interacting internal atomic electric degrees of freedom. Transitions are often broadened or rapidly transformed by complex mechanisms that are difficult to analyze and are not amenable to the predictions of the relatively simple Hamiltonians so useful in NMR. Pulsed coherent laser experimental techniques have not yet reached the stage of sophisticated high-resolution pulsed NMR spectroscopy, utilizing elaborate pulse sequences and double resonance methods, made possible by the persistence of coherent nuclear precession over relaxation times ranging widely from microseconds to many seconds.

As NMR is a predecessor of quantum optics, the molecular beam magnetic resonance method should be recognized as the predecessor of NMR. After space quantization of spin was confirmed by the Stern–Gerlach molecular beam deflection experiment,¹ a series of nonresonant type of molecular beam deflection experiments followed. Spins were measured directly, and magnetic moments were measured indirectly by combining laboriously acquired beam deflection data with theory known at the time. Of special interest was the effect of the apparent rotating magnetic field seen by an observer moving at the velocity of magnetic moments in a molecular beam as it passes through a static inhomogeneous field. For those molecules in the Maxwell spectrum that have just the right velocity, the static inhomogeneous field appears to rotate in partial synchronism with the Larmor frequency of spin precession determined by the main magnetic field. Therefore, the synchronism acts as a partial resonance and flips the spin. Rabi published the theory for this effect,² and in principle defined a magnetic resonance. The application of radiowave resonance excitation was not carried out by Rabi’s Columbia group immediately after Rabi’s paper was published. C. J. Gorter visited Columbia in 1937, and suggested to Rabi that it would be more efficient to apply a rotating radiofrequency field produced by an oscillator-driven inductance rather than rely on field inhomogeneity. This suggestion stimulated Rabi and his collaborators in 1937 to apply radiofrequency magnetic excitation to a beam of LiCl, and the magnetic resonance spectrum of the Li nucleus was obtained³ as the first coherent spectroscopic measurement in the history of physics, followed by a series of many ground-breaking resonance experiments. Although line broadening effects such as time of flight and field inhomogeneity did initially reduce the precision of molecular beam resonance spectroscopy, this first demonstration showed that spin resonance electromagnetic energy could be concentrated into a single coherent frequency by an oscillator, and led to the development of precision magnetic resonance and laser spectroscopy as it exists today.

For a number of years after the Bloch and Purcell groups^{4,5} initiated the science of NMR, it was not anticipated that the dynamic Bloch equations of NMR could describe as well the transient and steady state behavior of optical electric dipole resonance. Measurements of nuclear spins and magnetic moments were an early preoccupation. Studies were and still are focused upon lineshape, relaxation times, and high-resolution NMR spectra where the spins serve as probes of molecules, local fields, and fluctuations of the medium. Because the applied field energies and intensities usually far exceed total spin coupling energies and NMR signal intensities, applied rf fields are taken as constant. Therefore the direct role of cavity coupling to the spins in the resonance equations is

not a major consideration, although this coupling is necessary in order to observe NMR signals in the first place. In order to take into account the alteration of applied electric fields and free precession signals due to radiation damping caused by coupling with the cavity or the Poynting flux in free space in quantum optics, however, radiation damping must be considered of primary importance.

Tuned circuit cavity–spin coupling effects show up during free precession of the macroscopic nuclear magnetization in terms of coherent radiation damping.⁶ Slight effects of radiation damping of free induction signals are evident in magnetic resonance imaging, where magnetic fields are very homogeneous and relaxation times are long. Radiation damping in NMR is essentially ‘coherent overdamping’. The rate at which the cavity resistively dissipates power absorbed from the precessing magnetization usually far exceeds the rate at which power is emitted by the magnetization as it precesses about a reaction field H_1 in the rotating frame of reference. Radiation damping occurs only over the signal coherence lifetime T_2 (including the effect of inhomogeneous broadening as well as natural broadening), which is usually much shorter than the radiation damping time τ_r of the magnetization. Therefore the magnetization tips back by a slight amount toward alignment with the polarizing magnetic field. The radiation damping rate⁶ is given by $1/\tau_r = 2\pi Q\gamma M_0\xi$. Suppose the cavity losses become less and less, and the emission from the two-level system becomes greater and greater. Let any or all of the terms in the product of cavity figure of merit Q , magnetization M_0 , gyromagnetic ratio γ , and filling factor ξ be made large enough so that, instead of the usual condition $T_2 \ll \tau_r$, the approximate equality $\tau_r \approx T_2$ holds. This is the threshold condition that would make possible spontaneous NMR oscillations, applicable as well to the laser when translated into parameters of macroscopic electric dipole radiation. The final requirement is to maintain an inverted population of the two-level system, and the maser or laser is therefore invented with benefit of hindsight. The parameters expressed by $1/\tau_r$ reappear upon manipulation of optical Bloch–Maxwell equations, outlined later. The above conditions for laser oscillations indeed became the basis for the maser–laser principle, finally realized⁷ by Townes and by Basov and Prokhorov in 1954.

In 1954, Dicke⁸ stressed the idea of radiation coherence from an ensemble of phased electric dipole moments, applicable to the prediction of the dipole pattern of radiation from two-level systems other than magnetic spins. Formally, the incoherent spontaneous emission rate, proportional to N dipoles, can be distinguished from the coherent emission rate, proportional to N^2 , by inspecting the rules of angular momentum that apply to collective Bose states. Dicke pointed out that coherent superpositions of atomic two-level states attained by radiation-driven initial states could be prepared, just as in pulsed NMR, and that these states give rise to coherent dipole radiation. Following this work, a semantic trend developed in the literature in which the term ‘superradiance’ was applied to almost every process of coherent radiation from phased dipole arrays, particularly in coherent laser optics. Perhaps this happened because the direct application of optical Bloch equations had not yet been made, and it appeared as though the generation of coherent optical radiation was a unique phenomenon. However, it is standard knowledge from the Maxwell equations that coherent dipole source terms emit

power in proportion to N^2 , which ‘is’ superradiance, and is absolutely necessary, for example, to detect ordinary NMR signals. It would seem reasonable not to rename an old Maxwell phenomenon just because ‘superradiance’ rolls off the tongue so impressively. It is more à propos to apply the term to those special effects in which the initial incoherent spontaneous emission of power, proportional to N , finally evolves into the coherent emission condition^{8,9} where the power becomes proportional to N^2 .

From above, the obvious conclusion is that all NMR phenomena as we know them involve an enormous number of N dipoles prepared in phased arrays, where $N^{1/2} \ll N$. Likewise, many optical analogs of NMR are governed by this condition. There is therefore no need to supplement the semiclassical approach with quantum field theory in the majority of experiments involving macroscopic behavior, although it may be desirable in certain circumstances to deal with subtle aspects of fluctuations and spontaneous emission. Instead, spontaneous emission is introduced as a phenomenological damping term, just as the spin–lattice relaxation time T_1 appears in the Bloch equations.

In 1957, Feynman, Vernon, and Hellwarth¹⁰ showed that electric dipole transitions in a two-level system could be formulated using equations that were the analogs of the Bloch torque equations, originating from the density matrix. Although the discussion in their paper was restricted to a particular maser problem, they utilized the semiclassical method in which the atoms are quantized, but the radiation and applied fields become classical self-consistent solutions of the Maxwell and Schrödinger equations. The works of Jaynes¹¹ and Lamb¹² extended the semiclassical method to quantum maser and laser analysis. A number of treatments and reviews have appeared with the express purpose of clarifying and justifying the assumptions of the semiclassical approach. In a monograph by Bloembergen¹³ on nonlinear optics, the density matrix formulation commonly used in NMR is spelled out so that it may be applied more universally to optical systems, extending as well to multilevel systems. Allen and Eberly¹⁴ treat a number of topics in greater depth, some of which are briefly outlined in this article, particularly with regard to radiation damping as it pertains to photon echoes¹⁵ and self-induced transparency.¹⁶ The book by Shen¹⁷ covers modern topics in quantum optics, including transient phenomena related to NMR.

The discussion of NMR foundations in quantum optics that follows will not attempt to hew to the line of notation different from NMR introduced in the original papers and monographs referred to above. A one-to-one notation conventional in NMR will be carried over into a presentation of the optical Bloch–Maxwell equations. From them, certain parametric and phenomenological relationships between NMR and quantum optics will be pointed out.

2 THE RESONANCE EQUATIONS

The optical picture of NMR absorption was first introduced by the Harvard group.⁴ The Bloch equations⁵ of the Stanford group at first emphasized the nuclear induction dynamics of macroscopic nuclear polarizations, but of course these two approaches lead to the same interpretation of NMR. The rate equation for the population difference $n = N_1 - N_2$ between

the number of spins N_1 in the ground state and the number N_2 in the excited state is given by

$$\frac{dn}{dt} = \frac{n_0 - n}{T_1} - 2nR_{12} \quad (1)$$

In the high-temperature approximation $n_0/N \ll 1$ for spin $I = \frac{1}{2}$, the equilibrium population difference is given by $n_0 = N\hbar\omega_0/2kT$, where $N = N_1 + N_2$ is the total number of spins, $\omega_0 = \gamma B_0$, $\gamma = 2p/\hbar$ is the gyromagnetic ratio, and B_0 is the applied polarizing magnetic field. Note that coherence cannot be described by equation (1). The rate¹⁸ of rf absorption, expressed from standard perturbation theory,

$$R_{12} = \frac{1}{2}\pi\gamma^2 H_1^2 g(\delta) \quad (2)$$

tends to equalize the populations, while the spin-lattice relaxation rate T_1^{-1} tends to restore a population difference toward thermal equilibrium. The off-resonance parameter $\delta = \omega_0 - \omega$ appears in the normalized (assumed to be Lorentzian) lineshape function

$$g(\delta) = \left(\frac{T_2}{\pi}\right) \frac{1}{1 + \delta^2 T_2^2} \quad (3)$$

where ω_0 is the Larmor frequency and ω is the applied frequency of the rotating rf field modulus H_1 .

Equation (1) can now be modified so that it speaks the language of optics, useful later in devising the optical Bloch–Maxwell equations. The energy of the two level ensemble is first defined as $W = -\frac{1}{2}n\hbar\omega_0$, so that equation (1) becomes

$$\dot{W} = \frac{W_0 - W}{T_1} - 2WR_{12} \quad (4)$$

Substitution of $g(\delta) = T_2/\pi$ from equation (2) into equation (3), for $\delta = 0$, gives for the last term in equation (4),

$$2WR_{12} = \omega_0 H_1 v \quad (5)$$

The absorption component of magnetization $v = np\gamma H_1 T_2$ can be identified as a slowly varying solution at resonance for the linear unsaturated driven magnetization of the Bloch equations in the rotating frame of reference, transverse to the applied rotating field H_1 . The slowly varying longitudinal magnetization $M_z = np$ is directed along the polarizing field B_0 . In the Bloch equations, the v and W terms as written are time-dependent and valid on or off resonance. This generality may be adopted, and therefore the restricted on-resonance quasisteady state interpretations of v and W in equation (4) may be dropped. Instead, equation (4) becomes one of the coherence-dependent Bloch equations:

$$\dot{W} = -\omega_0 H_1 v + \frac{W_0 - W}{T_1} \quad (6)$$

valid for any δ , expressed in terms of the energy

$$\begin{aligned} W &= -M_z B_0 = -\frac{M_z \omega_0}{\gamma}, \\ W_0 &= -M_0 B_0 = -n_0 p \end{aligned} \quad (7)$$

2.1 Optical Bloch–Maxwell Equations

At this point, a jump in the interpretation of the Bloch equations can be made from the NMR of a two-level system to the resonance description of a two-level optical system. Now the polarizations representing absorption (v) and dispersion (u) are to be interpreted as electric source term functions of time t and distance z in the Maxwell equations of propagation. A pseudoelectric polarization may be defined as $P_z = -(\kappa/\omega_0)W$, with P_z replacing M_z , the ‘gyro-electric’ ratio $2p_0/\hbar = \kappa$ replacing γ , and the electric field modulus $\mathcal{E}$ replacing H_1 . The polarizations v and u are defined in the frame of reference rotating at the applied optical frequency ω of a plane wave

$$E(z, t) = 2\mathcal{E}(z, t) \cos[\omega t - kz + \phi(z, t)] \quad (8)$$

In the slowly varying wave approximation $\partial\mathcal{E}/\partial z \ll k\mathcal{E}$, $\partial\mathcal{E}/\partial t \ll \omega\mathcal{E}$, the field modulus $\mathcal{E}(z, t)$, u , v , W , and the phase shift $\phi(z, t)$ now appear as slowly varying parameters.

The optical analogue of the NMR torque equation in the rotating frame reads

$$\begin{aligned} \frac{d\mathbf{P}}{dt} &= \mathbf{P} \times [\mathbf{u}_0 \kappa \mathcal{E}(z, t) + \mathbf{z}_0(\delta\omega + \dot{\phi}(z, t))] \\ &\quad - \frac{\mathbf{u}_0 u + \mathbf{v}_0 v}{T_2} - \frac{\mathbf{z}_0(W - W_0)}{T_1} \end{aligned} \quad (9)$$

where $\mathbf{P} = \mathbf{u}_0 u + \mathbf{v}_0 v + \mathbf{z}_0 P_z$ is the total macroscopic electric polarization vector, and $\mathbf{u}_0$, $\mathbf{v}_0$, and $\mathbf{z}_0$ are the unit vectors of the axes in the rotating frame. The effective frequency and propagation terms are given by $\omega_e = \omega + \dot{\phi}(z, t)$ and $k_e = k + \partial\phi(z, t)/\partial z$, respectively. Instead of the pseudopolarization component P_z , the energy $W = -\frac{1}{2}n\hbar\omega_0$ is often the appropriate physical term to be used in the optical Bloch equations. In the absence of damping, the conservation condition

$$N^2 p_0^2 (u^2 + v^2) + \frac{\kappa^2}{\omega_0^2} W^2 = \frac{\kappa^2}{\omega_0^2} W_0^2 \quad (10)$$

applies, and, with damping, the optical Bloch equations are written out completely as

$$\dot{u} = v(\delta\omega + \dot{\phi}) - \frac{u}{T_2} \quad (11a)$$

$$\dot{v} = -u(\delta\omega + \dot{\phi}) + \frac{\kappa^2}{\omega_0} \mathcal{E} W - \frac{v}{T_2} \quad (11b)$$

$$\dot{W} = -v\mathcal{E}\omega_0 + \frac{W_0 - W}{T_1} \quad (11c)$$

The relaxation time T_1 here is assumed to be the inverse spontaneous emission rate. At equilibrium, the excited state of the optical two-level system is empty, and therefore the ground state population is $n_0 = N$ at the equilibrium condition $\hbar\omega_0 \gg kT$, in contradiction to the high-temperature approximation $n_0/N \ll 1$ applied in equation (1). However, the form of equation (11c) remains valid because the rate of change of population difference due to spontaneous emission in equation (4) can be written as

$$\frac{dn}{dt} = 2R_{\text{spont}} N_2 = R_{\text{spont}} (N - n) \quad (12)$$

so that the identity

$$\frac{W_0 - W}{T_1} = \frac{1}{2} R_{\text{spon}} (N - n) \hbar \omega_0 \quad (13)$$

may be retained in equation (11c) where $W_0 = -\frac{1}{2} N \hbar \omega_0$, $W = -\frac{1}{2} n \hbar \omega$, and $1/T_1 = R_{\text{spon}}$.

Equations (11a)–(11c) are time-dependent at a given position z , and include the effect of frequency modulation in the term $\phi(z, t)$. They are then connected with the Maxwell wave equation

$$\frac{\partial^2 E(z, t)}{\partial z^2} = \frac{\eta^2}{c^2} \frac{\partial^2 E(z, t)}{\partial t^2} + \frac{4\pi}{c^2} \frac{\partial^2 P_{u,v}(z, t)}{\partial t^2} \quad (14)$$

by assuming the slowly varying wave approximation expressed earlier, with the definition $P_{u,v} = (u + iv) \exp[i(\omega t - kz - \phi(z, t))]$. Therefore combining equations (11a)–(11c) with equation (14) yields

$$\frac{\partial \mathcal{E}(z, t')}{\partial z} = \frac{-2\pi\omega}{\eta c} \int_{-\infty}^{\infty} v g(\delta) d\delta \quad (15)$$

and

$$\mathcal{E} \frac{\partial \phi(z, t')}{\partial z} = \frac{2\pi\omega}{\eta c} \int_{-\infty}^{\infty} u g(\delta) d\delta \quad (16)$$

in the retarded frame of reference, where the retarded time $t' = t - \eta z/c$. Equations (11a)–(11c), (15), and (16) may apply to either sign of circular polarization (positive as shown) of the rotating $\mathcal{E}$ field modulus, satisfying the transition selection rule $\Delta m = \pm 1$. Oppositely rotating magnetizations excited by a linearly polarized field $\mathcal{E}_x(z, t)$, expressed by equation (8), involves the selection rule $\Delta m = 0$, and the magnetizations sum to produce a linearly polarized magnetization along the x axis in the laboratory frame as follows:

$$\begin{aligned} P_x &= P_{u,v}(+) + P_{u,v}(-) \\ &= u \cos \psi(z, t) - v \sin \psi(z, t) \end{aligned} \quad (17)$$

where $\psi(z, t) = \omega t - kz - \phi(z, t)$. The Bloch–Maxwell equations above can be generalized to cases where the two-level system is degenerate¹⁶ and not necessarily characterized by one dipole matrix element. In that case, u and v are replaced by sums $\sum_i u_i$, $\sum_i v_i$ corresponding to sums over the i matrix elements.

If equation (14) is applied without the slowly varying wave approximation, extra smaller terms of the type $\ddot{u}$, $\ddot{v}$, $\omega \dot{u}$, $\omega \dot{v}$, and $\omega \dot{v}$ would appear in equation (15) and (16) along with $\omega^2 u$ and $\omega^2 v$, which dominate. The smaller higher-order terms are of the same order of magnitude as the off-resonance response contribution by dipole matrix elements in the atom involving transitions to quantum levels other than the two-level system at or on resonance. Although other levels are not included, they must contribute in a formal sense, as dictated by the sum rule for optical response. Unless other levels are taken into account, it is quite possible to arrive at unrealistic conclusions concerning optical pulse propagation effects using extremely sharp and powerful laser pulses.

3 RADIATION DAMPING

The mechanism of radiation damping is essential for the detection of free precession signals in NMR and quantum optics. The coupling of precessing spin magnetization to the cavity (LCR tuned circuit) in NMR allows the spin system to radiate coherently into a cavity volume V_c with a single mode confined to a bandwidth $\Delta\nu = \nu/Q$, where the wavelength λ is much greater than the cavity and sample dimensions. The density of states is therefore $\rho_c = (V_c \Delta\nu)^{-1}$ whereas, with no cavity present, the magnetic dipole system would radiate incoherently because of vacuum field fluctuations $\mathbf{B}_{\text{vac}}$ at an infinitesimally small Einstein emission rate, given by

$$\frac{1}{\tau_E} = \frac{2\pi}{\hbar^2} \langle \mathbf{P} \cdot \mathbf{B}_{\text{vac}} \rangle \rho_F = \frac{32\pi^3 p^2}{\hbar \lambda^3} \quad (18)$$

where the free space density of states is $\rho_F = 8\pi \nu^2/c^3$. The connection between incoherent spontaneous emission rate of the dipole moment in free space to that in the NMR cavity is made by replacing the density of states ρ_E by $\rho_c = (V_c \Delta\nu)^{-1}$ in equation (18); i.e.,

$$\frac{1}{\tau_r} = \frac{N V_s}{\tau_E} \frac{\rho_c}{\rho_E} = 2\pi M_0 \gamma Q \xi \quad (19)$$

The NMR coherent emission rate in a cavity is enhanced by factors of $N V_s$ coherent spins and the cavity density of states ρ_c (which is much larger than ρ_E). In the LCR circuit, spin energy is dissipated under the condition $\gamma H_1 \gg R/L$, where $Q = \omega/\Delta\nu$, and the sample filling factor is $\xi = V_s/V_c$. The power emitted by the spins in terms of the voltage V_{ind} is given by

$$M_0 B_0 V_s \frac{d(\cos \theta)}{dt} = \frac{V_{\text{ind}}^2}{2R} = \frac{(4\pi M_0 \omega N_t \xi \sin \theta)^2}{2R} \quad (20)$$

where N_t is the number of turns in the inductance $L = 4\pi \times (N_t/l)^2 V_c$ of length l and volume $V_c = Al$, and $\Delta\nu = R/L$. From equation (20), the radiation damping equation is expressed as

$$\begin{aligned} \gamma H_1(t) &= -2\pi M_0 \gamma Q \xi \sin \theta = \dot{\theta} \\ &= -\frac{\sin \theta}{\tau_r} = -\frac{1}{\tau_r} \text{sech} \left(\frac{t + t_0}{\tau_r} \right) \end{aligned} \quad (21)$$

Following a θ_0 pulse at $t = t_0$, the magnetic moment M_0 precesses about the cavity reaction field $H_1(t)$ in the frame of reference rotating at frequency ω , and is tipped toward the external magnetic field direction at a later time to a smaller angle $\theta(t)$. If the spins remain in phase for a short time $T_2 \ll \tau_r$ after an applied $\theta_0 = \frac{1}{2}\pi$ pulse ($t = -t_0$), the spin energy $W_s = -M_0 B_0 \Delta\theta$ is given up to the cavity after a small decrease in angle $\Delta\theta \approx \gamma H_1 T_2 \approx T_2/\tau_r$. Therefore the emitted spin precession power immediately after the $\frac{1}{2}\pi$ pulse is

$$P_{\text{max}} = \frac{M_0 B_0 \Delta\theta}{T_2} V_s = \frac{M_0 B_0}{\tau_r} V_s = 2\pi Q M_0^2 \omega_0 \xi V_s \quad (22)$$

3.1 NMR Maser and Optical Laser Threshold Condition

Equation (21) can be adapted to a steady state interpretation of an NMR maser by postulating that $M_0 \rightarrow -M_0$, and the

spin population is maintained in an inverted steady state. The field $H_1 = \theta/\gamma$ is now time-independent instead of a transient, and the steady state condition at resonance for the transverse magnetization in equation (21) requires the conversion

$$-M_0 \sin \theta \rightarrow v = \frac{-M_0 \gamma H_1 T_2}{1 + (\gamma H_1)^2 T_1 T_2} \quad (23)$$

obtained from the steady state solution of the Bloch equations, which includes the saturation denominator. Substitution of equation (23) in place of $M_0 \sin \theta$ in the first equality of equation (21), yields the relation $H_1 = v/\gamma \tau_r M_0$, and therefore

$$(\gamma H_1)^2 T_1 T_2 = \sqrt{-1 + T_2/\tau_r} \quad (24)$$

This very simple macroscopic relation shows that the NMR ‘maser’ field H_1 can only be sustained as a real quantity when the condition $T_2/\tau_r \geq 1$ applies at threshold. Obviously, equation (24) cannot take into account statistical properties at threshold due to noise, nor does it properly take into account the gain in H_1^2 when the condition $T_2/\tau_r > 1$ is obeyed. In a qualitative sense, this threshold condition defines a phase transformation boundary between the incoherent spontaneous emission phase and coherent emission phase.

In terms of optical parameters, equation (24) satisfies the threshold condition as well for laser action. For later reference, the optical Bloch equation, equation (11c), is now written using optical parameters:

$$\dot{W} = -\omega \kappa \tau_{ro} P_o \mathcal{E}^2 - \frac{W - W_0}{T_1} \quad (25)$$

where

$$\mathcal{E} = \frac{P_o \sin \theta}{P_o \kappa \tau_{ro}} = \frac{v}{P_o \kappa \tau_{ro}} \quad (26)$$

and the optical damping time τ_{ro} , now governed by feedback in an optical cavity, replaces τ_r . The definition equation (26) is analogous to $H_1 = v/\gamma \tau_r M_0$ expressed by equation (23) in the case of NMR. Note that $\mathcal{E}$ can only be interpreted as a reaction field in equation (25) and not an applied field. In the weak perturbation limit, the saturation denominator in v is absent, and any dependence of $\mathcal{E} = v/P_o \kappa \tau_{ro}$ on T_1 is included only by its effect on T_2 . In the next section, the damping time τ_{ro} will pertain to optical coherent emission in the absence of cavity feedback.

4 OPTICAL FID AND THE PHOTON ECHO

In terms of the transverse polarization v , a sample of radiating electric dipoles is prepared in cooperative phase by a traveling wave short pulse (or two pulses in succession to obtain a photon echo), and thereafter emits an optical FID signal. The sample length l is much shorter than the linear absorption length

$$\alpha^{-1} = \left(\frac{8\pi N p_0^2 \omega T_2}{\hbar \eta c} \right)^{-1} \quad (27)$$

This restriction avoids the possibility of nonlinear propagation effects such as self-induced transparency,¹⁶ in which case

the applied pulse itself is modified in shape, amplitude, and velocity as it transmits through the sample. [The absorption coefficient α is obtained from equation (11c) and (15) in the homogeneous line limit by combining the relations $(\eta c/4\pi) \partial \mathcal{E}^2 / \partial z = \dot{W}$ and $v = N p_0 \kappa \mathcal{E} T_2$, and dropping the last term in equation (11c) in the weak perturbation limit that $W \approx W_0$. Here the field $\mathcal{E}$ is interpreted as an applied field.] The reaction field $\mathcal{E}$ in equation (25) is now interpreted as the electric FID signal radiated by the polarization v that remains in phase for a coherence time t_p , shorter than T_1 . Because the cooperative emission rate is enhanced over the spontaneous rate term $(W - W_0)/T_1$ in equation (25), this term is dropped. The conservation relation

$$\frac{nc}{4\pi} \mathcal{E}^2 = \dot{W} l \approx \mathcal{E}^2 \omega \kappa \tau_{ro} P_o l \quad (28)$$

now defines the flux per unit area passing out of a sample of length l . This flux represents a power loss analogous to the radiation damping Ohmic loss in the NMR case of radiation damping. Coherent radiation is directed along l , and the emission rate $1/\tau_{ro}$ is defined from the identity equation (29) as

$$\frac{1}{\tau_{ro}} = 2\pi P_o \kappa \omega \frac{2l}{\eta c} = \frac{1}{\eta \tau_E} N V_{coh} \quad (29)$$

This rate depends on the free space spontaneous emission rate $1/\tau_E$ given by equation (18). There is no cavity feedback, but there is emission enhancement by a factor of the number of phased dipoles contained in a coherence volume defined by $V_{coh} = \lambda^2 l / 2\pi$. In the case of NMR, the wavelength is large compared with the sample dimensions, and therefore the coherence volume is given by the entire sample volume $V_s = \xi V_c$ as it appears in equation (19). In the optical FID case, the wavelength is much less than the sample dimensions, and therefore the radiation rate is determined by a much smaller coherence volume V_{coh} instead of V_s .

Before Hartmann and his collaborators¹⁵ obtained photon echoes, there was a period of time when the coherent FID emission rate was predicted to be much too large. This resulted because the sample volume V_s was used in place of the coherence volume V_{coh} in equation (29). The optical FID pulse burst of power or ‘optical bomb’⁸ was expected to be as short as 10^{-13} s or shorter—a number intimidating enough to make experimentalists believe that the FID would be just about impossible to observe. The much longer observed times of photon echo bursts extend from about 10^{-8} s to 10^{-6} s.

Laser pulse coherent transient experiments often require pulses shorter than spontaneous emission times, of order 10^{-9} – 10^{-8} s, so that the initial tipping angle $\theta_0 \approx \theta(t) \ll 1$ must be small if laser output power is limited. Also, the optical line is usually inhomogeneously Stark electric or Doppler broadened, and only a small fraction ($\approx T_2^*/t_p$) of the N atoms in the line is excited spectrally, where t_p is the pulse width. Therefore the number of dipoles actually excited is given by $n \approx N \theta(t) T_2^*/t_p$. These dipoles contribute from an optical spectral width of about $1/t_p$ within the optical line, and the emitted electric field in equation (25) appears in the form of a transient FID or a photon echo¹⁵ lasting about t_p . Using equation (26), equation (28), may be rewritten to express the FID pulse power emitted by a volume Al of the sample:

$$\dot{W}Al = \frac{v^2}{\hbar P_o \kappa \tau_{ro}} Al \quad (30)$$

The number of photons $N_{\text{ph},A}$ emitted per unit area by an electric dipole FID lasting for t_w from n dipoles in coherent superposition is given by

$$\begin{aligned} N_{\text{ph},A} &= lt_w \dot{N}_{\text{ph}} = \frac{lt_w \dot{W}}{\hbar \omega_0} = \frac{v^2}{\hbar P_o \kappa \tau_{ro}} \frac{lt_w}{\hbar \omega_0} \\ &= \frac{8\pi^2 p_o^2 l^2 n^2 t_w}{\eta \hbar \lambda} \end{aligned} \quad (31)$$

$$N_{\text{ph},A} \approx \frac{8\pi^2 p_o^2 l^2 N^2}{\eta \hbar \lambda} \frac{T_2^{*2} \theta^2}{t_w} \quad (32)$$

Note that the coherence volume V_{coh} in equation (29) appears naturally in the application of the optical Bloch equations, and does not have to be introduced explicitly.

4.1 Role of the Reaction Field During Linear Propagation

The concept of the reaction field is connected with induced absorption and emission during steady state propagation. Consider linear absorption (no saturation denominator in ν) through a two-level medium where the propagating beam intensity is given by $\mathcal{E}^2(z) = \mathcal{E}^2(z=0)e^{-\alpha z}$. The reduction in field amplitude over a short distance $\Delta z = l$ at position z is given by $\Delta \mathcal{E} \approx -\frac{1}{2}\mathcal{E}\alpha z$. Substitution of α from equation (27) and $\mathcal{E} = \nu/P_o \kappa T_2$ into this expression for $\Delta \mathcal{E}$ shows that it is identical to the reaction field given by equation (26), where $1/\tau_{ro}$ is given by equation (29). If the incoming driving field $\mathcal{E}$ that induces the steady state polarization ν is cut off abruptly then ν will radiate an initial FID field $\Delta \mathcal{E}$ identical

to the reaction field that existed before $\mathcal{E}$ was cut off. The $\Delta \mathcal{E}$ fields add in phase over the entire sample to provide a total optical FID signal at the exit end of the sample. Similarly, if the two-level system is maintained in the inverted state, acting as a traveling wave amplifier, $\Delta \mathcal{E}$ will represent a gain in field amplitude, with the FID signal shifted in phase by 180° following the abrupt cut-off.

4.2 Two-Pulse Photon Echo Phase Matching Condition

The two-pulse photon echo is obtained in practice after a first $\theta_1, \mathbf{k}_1$ pulse, propagating in the z direction, is followed by a second $\theta_2, \mathbf{k}_2$ pulse applied in a slightly different direction by a small angle ξ . The $\mathbf{k}$ propagation directions now play an important role. It will be seen that the photon echo signal¹⁵ is emitted and detected in a third $\mathbf{k}_{\text{echo}}$ direction, deviating by small angle 2ξ with respect to z . This property conveniently avoids saturation of the optical detector by the applied laser pulses along the $\mathbf{k}_1$ and $\mathbf{k}_2$ directions. In a given volume element $A\Delta z$ at z , the rotating electric laser modulus $\mathcal{E}$ is shifted in phase angle by $\vartheta = (k_1 - k_2)z$ relative to its alignment in the rotating frame during the first pulse. In the NMR case for a two-pulse echo, if the θ_2 pulse is applied at a rf phase shift ϕ with respect to the phase of the θ_1 pulse then the phase shift of the echo signal is 2ϑ relative to the echo that occurs when both pulses are in phase.¹⁹

The photon echo is now described only with regard to its z dependence as it propagates. Integration must be carried out over all the signals emitted from given volume elements $A\Delta z$ extending from $z = 0$ to $z = L$, the length of the sample. Phase dependences $k_1 z$, $k_{\text{echo}}(L - z)$, and $2\phi = 2(k_1 - k_2)z$ account respectively for the phased array set up along z by the first pulse, the phase change of the echo emitted from volume element $A\Delta z$ at z to L , and the phase shift caused by the shifted direction of the second pulse. The result for $\xi \ll 1$ is

Table 1 Effects and Concepts From NMR That Occur in Quantum Optics

Linear and nonlinear absorption and dispersion; saturation, hole burning, and spectral and spatial diffusion
Homogeneous and inhomogeneous broadening
Radiation damping; coherent reaction field dynamics
Rabi flop; precession about the effective field in the rotating frame (optical nutation)
Adiabatic following and inversion
Photon echo, rotary photon echo, three-level echoes, transfer of coherence, single pulse free precession (FID)
Stimulated echo pulse holographic memory storage in rare earth crystals
Coherent quantum beats; stimulated heterodyne coherent Raman beats, coherent Raman scattering
Self-induced transparency
Two-photon transition phenomena; AC Stark effect; multiple quantum transitions
Electric rotary saturation
Double resonance
Two-level laser theory and operation
Optical four-wave mixing, stimulated echo, backward-wave echo
Optical phase conjugation
Fourier transform spectroscopy
Optical pulse chirping, frequency modulation
Relaxation dynamics, motional narrowing, dipole-dipole coupling
Autler Townes effect; dressing of atomic levels, fast driven precession averaging
Holography, grating scattering
Nuclear polarization by optical pumping, spin exchange

$$\begin{aligned}
 E_{\text{echo}}(L) &\propto \int_0^L e^{2i(k_1 - k_2)z - ik_1 z - ik_{\text{echo}}(L-z)} dz \\
 &= \frac{\sin\{\frac{1}{2}[k_{\text{echo}} - (2k_2 - k_1)]L\}}{\frac{1}{2}[k_{\text{echo}} - (2k_2 - k_1)]L} \quad (33)
 \end{aligned}$$

Since the magnitudes of the two-pulse $\mathbf{k}$ vectors ($|\mathbf{k}_1| = |\mathbf{k}_2|$) are the same in the usual experiment, the phase matching condition above cannot be satisfied exactly, given that the direction of $\mathbf{k}_2$ is chosen at a small angle ξ with respect to the z direction of $\mathbf{k}_1$. If ξ were not small, the phase factor in the integrand in equation (33) should be written as $\exp[i[\mathbf{k}_{\text{echo}} - (2\mathbf{k}_2 - \mathbf{k}_1)] \cdot \mathbf{r}]$, which in principle would require integration over all dipoles at points over $\mathbf{r}$ in the sample. Since we ignore diffraction from a strip of dipoles along $\mathbf{r} = z$, it is seen for $\xi \ll 1$ that $[\mathbf{k}_{\text{echo}} - (2\mathbf{k}_2 - \mathbf{k}_1)] \cdot \mathbf{r} \approx (k_1 - |2\mathbf{k}_2 - \mathbf{k}_1|)z \cos 2\xi$, where the maximum photon echo amplitude is emitted at an angle of approximately 2ξ with respect to the $\mathbf{r} = z$ direction when $\mathbf{k}_{\text{echo}}$ is parallel to $2\mathbf{k}_2 - \mathbf{k}_1$. However, because $|\mathbf{k}_1| = |\mathbf{k}_2|$, the propagation vector triangle cannot form an exact closed triangle, and the intensity of the photon echo is therefore reduced by a very small factor. The important point is that the photon echo is emitted in the $\mathbf{k}_{\text{echo}}$ direction at an angle of approximately 2ξ with respect to the $\mathbf{k}_1$ direction along z in order to avoid the blanking effect of the applied laser pulses.

There is a connection between the various types of photon echo production in the time domain and steady state nonlinear optical effects¹⁷ such as four-wave mixing and phase conjugation. Propagating phonon backward-wave

acoustic echoes observed by Shiren²⁰ are identically phase-conjugated echoes. The phase-conjugated echo represents an apparent reversal in time, because δ is effectively changed in sign in the precession phase δt . In addition, the sign of the $\mathbf{k}$ vector in the propagation phase kz is reversed, and the echo travels in the reverse z direction instead of the usual forward direction of applied pulses. These effects occur because pulse echoes are caused by nonlinear transformations imposed upon the Bloch vectors during applied pulses. As laser pulse sequences are conceived to merge with one another into the steady state, considerations of nonlinearity¹⁷ persist, but in a different form.

5 PRINCIPAL EFFECTS COMMON TO NMR AND QUANTUM OPTICS

A number of the most important NMR effects and concepts that appear in quantum optics can be listed (Table 1). However, it is sometimes difficult to make clear one-to-one relationships between the two fields. The basic physics of the Bloch–Maxwell equations, together with general application of the density matrix to more than two quantum levels, encompass a large number of phenomena in both fields. Many items are not listed that involve spontaneous emission, certain propagation effects, and some multilevel Raman processes, all having only remote connections to NMR. Parametric conversion effects are also omitted. No doubt there are some topics overlooked that deserve listing; or, vice versa, some

Figure 1 Various routes of analysis in quantum optics, including quantum electrodynamics (QED). The semiclassical (SC) method connects the Maxwell equations to various polarization source terms. The Bloch–Maxwell equations are designated by coupling the Maxwell equations to the optical Bloch equations adapted from NMR

items appearing may not deserve recognition in the opinion of some people. Rather than give references for each item, the reader is referred to standard reviews in the literature. For examples, books by Shen,¹⁷ Yariv,²¹ Sargent, Scully, and Lamb,²² Bagguley,²³ and Allen and Eberly¹⁴ treat many modern topics in quantum optics.

6 CONCLUSIONS

This brief review has covered only a few fundamental concepts of spontaneous coherent dipole radiation that connect NMR to quantum optics. The block diagram of Figure 1 suggests how the Bloch–Maxwell equations tie in with various routes of analysis that cover a broad number of topics in the literature. The figure shows the path of a frequently used perturbation approach, carried out without employing the Bloch equations, by taking the $\cdots \rightarrow$ route. Instead of using the Bloch equations directly on a par with the Maxwell equations, perturbation terms are inserted directly into the Maxwell equations. However, by taking the $---\rightarrow$ route, all orders of perturbation in principle are included simultaneously from these equations when they are directly coupled to the Bloch equations. Although full theoretical rigor is not always satisfied when the Bloch–Maxwell equations are used, they are helpful in providing phenomenological predictions. Figure 1 includes diagrammatically the role of other degrees of freedom and mechanisms involved in quantum optics, and indicates how experiments analyzed using quantum electrodynamics (QED) take a different route.

1 INTRODUCTION

Radiofrequency pulses are the major tool in modern nuclear magnetic resonance. In the simplest case, they are used to excite a free induction decay, which is then Fourier transformed to provide a spectrum. Even when there is no interest in the dynamics of the spins and all we want is a simple spectrum, this has many advantages over the classic continuous wave (CW) NMR. Sensitivity is increased owing to the fact that we observe all the spectrum all the time (see *Fourier Transform Spectroscopy*). Also, a pulse experiment gives us an instantaneous picture of the whole spectrum, so that we can follow kinetics and relaxation. Except when the cost of the instrument is an important factor, pulse spectrometers are always used to acquire spectra.

Pulses can do much more. The routine acquisition of spectra is just one example of the response of spin systems to rf pulses. The normal one-dimensional spectrum is only a small part of the information about a spin system. Because of the coherent nature of NMR, the spectrum can be manipulated by a series of pulses to produce a wide range of experiments. Many of the experiments are multidimensional (see *Multidimensional Spectroscopy: Concepts*). For example, chemical shift information can be passed from one nucleus to another for detection (see *COSY Two-Dimensional Experiments* and *Heteronuclear Shift Correlation Spectroscopy*), or chemical shifts can be separated from couplings (see *Two-Dimensional J-Resolved Spectroscopy*). Spin systems have many unobservable multiple quantum transitions, and these can be measured by pulse techniques. The basis of all these experiments is the response of a nuclear spin system to rf pulses.

In this article, we start with the basic interactions and draw on some results from the Bloch equations. These can be used to predict transient response, but it is usually assumed that in a pulse spectrometer, the rf magnetic field dominates all the other magnetic interactions. In this case, an rf pulse is usually equivalent to a rotation of the frame of reference through some angle called the flip angle. In simple cases, this is equivalent to a vector picture of magnetizations in three-dimensional space. These vector pictures can be very useful, particularly for pulse sequences used in imaging. For scalar-coupled spin systems,

the vector picture breaks down, and the actual behavior may be quite unexpected. For such systems, theory and simulations provide some insight into the behavior. Beyond these systems are those with strong interactions, such as quadrupolar nuclei, in which the rf does not dominate. Further complications arise in these cases. This article cannot cover all the responses of all spin systems to all types of pulses, but we follow the important and characteristic examples.

2 BASIC INTERACTIONS

Nuclear spins have magnetic moments, which interact with magnetic fields. This includes not only the static magnetic field in which NMR is done, but also any oscillating magnetic fields associated with electromagnetic radiation. In all cases, the interaction is given by the Hamiltonian

$$\mathcal{H} = -\boldsymbol{\mu} \cdot \mathbf{B} \quad (1)$$

where $\boldsymbol{\mu}$ is the nuclear magnetic moment and $\mathbf{B}$ is the magnetic field. Both of these are vector quantities, and the energy resulting from their interaction is the scalar product of the two vectors. This is the basic Hamiltonian.

The magnetic moment of a spin can be considered to arise from its angular momentum character. The physics of angular momentum means that the motion of the spins can be quite complex. In the simplest case when the magnetic field is static, or effectively so, the result of this interaction is that the spins will precess around the magnetic field. The frequency of this precession is ω_0 , the Larmor frequency, which is given by

$$\omega_0 = \gamma B_0 \quad (2)$$

If the magnetic field is oscillating in a plane then it can be made effectively static by going to a frame of reference rotating at the oscillation frequency. If the field as a function of time is given by

$$\mathbf{B}_1(t) = B_1 \cos(\omega t) \quad (3)$$

then this can be reexpressed as

$$\mathbf{B}_1(t) = B_1(e^{i\omega t} + e^{-i\omega t})/2 \quad (4)$$

The oscillating magnetic field is replaced by the sum of two counter-rotating fields. If the oscillation is near resonance with the Larmor frequency then in the frame of reference rotating with the rf magnetic field, the spins experience a field that is almost static. More precisely, they interact with an effective magnetic field shown in Figure 1.

The effective field is given by the vector sum of the rf magnetic field $\mathbf{B}_1$ in the (x, y) plane and the magnetic field that corresponds to the difference between the frequency of the rf, ω , and the Larmor frequency, ω_0 . In the rotating frame of reference, spins will precess around the effective magnetic field. Typical values for B_1 range from very small up to 10 mT. In terms of precession frequencies around $\mathbf{B}_1$, these values correspond to frequencies of less than 1 Hz up to the order of 100 kHz. For a spin- $\frac{1}{2}$ nucleus in a liquid, the $\mathbf{B}_1$ field is usually assumed to dominate other terms in the Hamiltonian, although

Figure 1 The effective field that spins experience in the rotating frame of reference. The field is the vector sum of the rf magnetic field B_1 and the magnetic field corresponding to the difference in frequency between the Larmor frequency of the spin, ω_0 , and the frequency of the rf, ω . (Here k is the unit vector along the z axis)

this is by no means always true. For solids and quadrupolar nuclei, this seldom holds, since dipolar and quadrupolar terms can be of the order of megahertz. However, the approximation that the rf can be represented as a static magnetic field in the (x, y) plane of a rotating frame of reference works very well in most cases.

Two cases of the interaction of spins with rf fields arise: the continuous irradiation (CW for continuous wave) case and the pulse response. This is an oversimplification, but it is convenient for our purposes here. In the first case we are mainly concerned with a steady state that the spin system achieves during irradiation, whereas the transient response to a pulse is most important in the second. One of the differences between the two cases is the treatment of spin relaxation. In the pulse case, relaxation is almost always ignored, whereas in the CW case, we are usually interested in the steady state achieved between the rf perturbation and the relaxation trying to reestablish equilibrium.

3 CONTINUOUS WAVE RADIOFREQUENCY

The critical parameter with CW NMR is whether or not the radiofrequency irradiation is saturating. If γB_1 is much smaller than the rate of spin relaxation $1/T_1$ then the field is nonsaturating. The rf power typically used in this case is quite low—of the order of milliwatts—and γB_1 is 1 s^{-1} or less. This is the case under normal operating conditions in a CW NMR spectrometer.

The Bloch equations provide a description of spin behavior under rf irradiation. They give the equations of motion for the three components of the magnetization for a single spin- $\frac{1}{2}$ in the presence of an rf magnetic field. By convention, the z component is defined as M_z , but the x and y components in the rotating frame of reference are called u and v . The u mode (dispersion mode) is in phase with the rf, and v is $\frac{1}{2}\pi$ out of phase, and is called the absorption mode. The coupled

differential equations defining these magnetization components are

$$\frac{du}{dt} = (\omega_0 - \omega)v - \frac{u}{T_2} \quad (5)$$

$$\frac{dv}{dt} = -(\omega_0 - \omega)u + \gamma B_1 M_z - \frac{v}{T_2} \quad (6)$$

$$\frac{dM_z}{dt} = -\gamma B_1 v - \frac{M_z - M_0}{T_1} \quad (7)$$

In the steady state, the solution to the Bloch equations is

$$u = M_0 \frac{\gamma B_1 T_2^2 (\omega_0 - \omega)}{1 + T_2^2 (\omega_0 - \omega)^2 + \gamma^2 B_1^2 T_1 T_2} \quad (8)$$

$$v = M_0 \frac{\gamma B_1 T_2}{1 + T_2^2 (\omega_0 - \omega)^2 + \gamma^2 B_1^2 T_1 T_2} \quad (9)$$

$$M_z = M_0 \frac{1 + T_2^2 (\omega_0 - \omega)^2}{1 + T_2^2 (\omega_0 - \omega)^2 + \gamma^2 B_1^2 T_1 T_2} \quad (10)$$

Note that this solution is valid for all values of B_1 —whether or not the rf is saturating depends on whether the term $(\gamma B_1)^2 T_1 T_2$ is much greater than or much less than 1.

Under nonsaturating conditions, the magnetization is only slightly perturbed away from equilibrium, as shown in Figure 2. If the rf is assumed to lie along the x axis then it exerts a torque on the magnetization, forcing it away from the z axis towards y . This is counterbalanced by relaxation, which tends to take the magnetization back to z . The steady-state magnetization is tipped slightly away from equilibrium towards the y axis. The receiver picks up the xy component of the magnetization, which in this case is out of phase with the rf. This gives a faithful representation of the ‘slow passage’ spectrum. Provided the field is nonsaturating, the y component will increase linearly with the strength of the rf field. These are the classic results from the Bloch equations.

Figure 2 Schematic illustration of the steady state magnetization of a single spin during weak continuous irradiation, as described by the Bloch equations. The rf magnetic field exerts a torque on the magnetization, tilting it away from the z axis

On a modern pulse Fourier transform spectrometer with a single coil probe, we often want to apply continuous irradiation during acquisition, for decoupling of homonuclear systems. The irradiation cannot be left on during the actual acquisition, since it would swamp any observed signal. In practice, the homonuclear irradiation is time-shared with the sampling of the digital points. For each point of the FID, the signal is sampled, the receiver is gated off, and the irradiation is turned on for a small part of the dwell time between sampling points. Typically, the duty cycle for the decoupler is 10%. Therefore, this continuous irradiation is really an infinite series of short, weak pulses. Provided the flip angle of each individual pulse is much less than 1 rad, this is equivalent to continuous irradiation at the same average power.¹

As well as the steady-state response to CW irradiation, there are transient effects that follow the change in rf power or frequency. Some examples are the ringing of a signal after the rf has swept past, the techniques of adiabatic rapid passage, and the observation of Torrey oscillations. The Bloch equations can also describe these effects, but the applications for which they are used are now better served by pulse methods.

4 PULSED RADIOFREQUENCY

4.1 Fundamentals

In this case, the rf power and the associated magnetic field are usually as large as possible. The aim here is usually to dominate all of the terms in the Hamiltonian, so that the main term is the precession about the rf magnetic field. Radiofrequency powers range up to a few kilowatts, and values of γB_1 are tens or hundreds of kilohertz. If the rf field is large enough, it will affect all of the spectrum uniformly. The

spectrum will be distorted if different parts of the spectrum experience different effective fields.

The effect of a strong pulse is very simple. The Bloch equations show that the field induces a torque on the spins. A pulse rotates the frame of reference through some flip angle α . *Note that this is not the same as rotating the magnetizations through a flip angle of $-\alpha$.* For the simple case of a single line spectrum, this distinction is not important, and the usual simple vector picture can be used successfully to rationalize the behaviour of spin systems. For more complex homonuclear coupled spin systems, the behavior of the magnetizations when the frame of reference is rotated can be quite counterintuitive.

The complex behavior of coupled spin systems can be rationalized by saying that both the spin that is being observed and the spin that is causing the splitting are experiencing the rotation simultaneously. Not only is the observed magnetization being rotated, but also the interaction that splits the magnetization is changing with the rotation. Because the rf field dominates all the terms in the Hamiltonian, values of the coupling constants and chemical shifts are irrelevant to the pulse response. It is the fact that the different parts of the multiplet are separated and may have different intensities and phases that is important.

One example of this behavior is the case in which intensities within a multiplet are distorted,²⁻⁴ as in Figure 3, or some CIDNP experiments (see *Chemically Induced Dynamic Nuclear Polarization*). In a doublet due to homonuclear coupling, the two lines do not behave as two vectors. Rather, the pulse acts on the sum of the two lines and their difference. In particular, the differences amongst members of a multiplet usually offer the best means of manipulating a spin system. This is why many pulse sequences use delays of $1/2J$ to maximize the difference magnetization in a doublet. If we are looking at an equilibrium spectrum, it shows none of this flip angle dependence. This is because, as far as the pulse

Figure 3 Illustration of flip angle effects on spectra when intensities within a multiplet are distorted. The diagram shows spectra of the methylene quartet in ethyl acetate as a function of flip angle. Prior to observation, the low-frequency inner peak of the quartet had been partially saturated. The small flip angle spectrum accurately reflects this, but the spectra with flip angles larger than $\frac{1}{2}\pi$ actually have the saturated line as apparently the most intense

is concerned, the equilibrium spectrum is a single density matrix element, no matter how complex the spectrum. It is the deviations from equilibrium that cause the flip angle dependence.

Because the exact behavior of a spin system can be obscure, several mathematical formalisms and simulation tools have been developed to help in our understanding.^{5–7} These provide complete and rigorous ways of calculating the density matrix as a function of time. The density matrix can be regarded in many ways: an element can be thought of as a transition, a magnetization, an operator, or a quantum mechanical coherence. All are different ways of looking at the same quantity. A good mathematical description means that we can follow not only the observable magnetizations, but also the unobservable multiple quantum coherences that form important parts of many pulse experiments.

All the formalisms do essentially the same job of providing a solution to the equation of motion of the density matrix, and the differences are mainly in the approach to the problem. One powerful tool is the use of angular momentum properties of the spin system. These provide a basis for using spherical tensors, since spherical tensors are a natural and general way of describing what happens to a system when the frame of reference is rotated. The details of these formalisms are far beyond the scope of this article, but a simple example of the treatment of a system of spin- $\frac{1}{2}$ nuclei is as follows.

For a single spin- $\frac{1}{2}$ system, there are four spin operators that define the system: the unit operator $\hat{1}$ and $\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$, representing the x , y and z components of the magnetization. For experiments that only involve pulses that are multiples of $\frac{1}{2}\pi$, the effect of a pulse on these operators is simple. A pulse along the x axis takes the z component $\hat{I}_z$ onto the y axis, takes $\hat{I}_y$ onto $-\hat{I}_z$, and leaves $\hat{I}_x$ alone. For more complex spin systems, products of these spin operators, one for each nucleus, can be manipulated in the same way. For instance, the product operator $\hat{I}_z\hat{I}_y$ represents a coherence associated with the second spin. A pulse along x turns this into $\hat{I}_y\hat{I}_{-z}$, which is coherence on the first spin, so coherence has been transferred. This provides a quick and convenient way of analyzing pulse sequences.

In order to describe a general pulse, of any flip angle or phase, the spin operators can be combined as follows to create spherical tensors:

$$\left. \begin{aligned} |0\rangle &= \frac{1}{\sqrt{2}}\hat{1} \\ |1_{+1}\rangle &= -(\hat{I}_x + i\hat{I}_y) \\ |1_0\rangle &= \sqrt{2}\hat{I}_z \\ |1_{-1}\rangle &= \hat{I}_x - i\hat{I}_y \end{aligned} \right\} \quad (11)$$

The notation $|M_m\rangle$ means an angular momentum (superspin) with total angular momentum quantum number M , and z component m .⁶ The utility of this approach is that the effect of any rotation about any axis is given by the appropriate Wigner matrix. For the three elements in equation (11) with superspin 1, the effect of a rotation about the y axis through an angle α is given by

$$\begin{bmatrix} \sin^2 \frac{1}{2}\alpha & \sqrt{\frac{1}{2}} \sin \alpha & \cos^2 \frac{1}{2}\alpha \\ \sqrt{\frac{1}{2}} \sin \alpha & \cos \alpha & -\sqrt{\frac{1}{2}} \sin \alpha \\ \cos^2 \frac{1}{2}\alpha & -\sqrt{\frac{1}{2}} \sin \alpha & \sin^2 \frac{1}{2}\alpha \end{bmatrix} \quad (12)$$

In the simplest case, a z magnetization corresponding to $|1_0\rangle$ is tipped down to form an xy magnetization proportional to $\sin \alpha$ and leaves a z magnetization proportional to $\cos \alpha$. More complex cases can then be described by products of Wigner matrices. This approach, using the angular momentum properties, also helps in calculating the effect of phase changes in the rf.

4.2 Phase of the Radiofrequency Pulse

The phase of an rf pulse defines the position of the rf magnetic field in the (x, y) plane (see **Phase Cycling**). The phase angle is the azimuthal angle between $\mathbf{B}_1$ and a reference, say the x axis. The absolute phase is irrelevant, but the relative phases of rf pulses in a sequence are critical, as well as their individual flip angles. For instance, a $\frac{1}{2}\pi$ pulse around the x axis, followed by a $\frac{1}{2}\pi$ pulse around y , has quite a different effect on a vector than a pair of $\frac{1}{2}\pi$ pulses around x . Most pulse experiments employ some sort of phase cycling sequence—repeating the experiment with the same values of the flip angles but with different rf phases. Phase cycling plays a crucial role, since it offers a good way of selecting coherences that we need, and eliminating unwanted signals.^{8,9} Until magnetic field gradients became common, phase cycling was the only way to do this.

Pulses are somewhat indiscriminate in their action, since there are no selection rules as to how many orders of multiple quantum coherence can be created. If there are N coupled spins $\frac{1}{2}$ then a density matrix element can have a coherence level (a number that counts the number of quanta involved in the associated transition) anywhere from $-N$ to $+N$ in integral steps. A general pulse acting on a general spin state will take coherence from anywhere in that range to anywhere else. Phase cycling tidies this up.

When an rf pulse is applied, it usually changes the coherence of a density matrix element. For instance, it will take z magnetization⁸ (no coherence, coherence level 0) into xy magnetization (single quantum coherence, coherence level ± 1). In general, this change in coherence level is by an amount Δm . When the phase of the rf pulse is changed by an angle ϕ , then coherence is changed by a phase factor $e^{i\Delta m\phi}$.¹⁰ One of the simplest examples is the P-type versus N-type peak selection in COSY. When, in a second acquisition, the mixing pulse is shifted by $\frac{1}{2}\pi$, the P type has a phase factor of $+1$, but the N type has a factor of -1 . Subtraction of the two spectra cancels the P-type peaks. This is the simplest type of phase cycling, and, for experiments with many pulses, the complete phase cycling sequences can get much longer.

4.3 Weak Pulses

The next question that arises is what happens when the rf magnetic field no longer dominates the other terms in the Hamiltonian. For instance, a $10\mu\text{s}$ pulse corresponds to

Figure 4 The effects of a weak pulse on a single line spectrum as a function of offset from resonance. The first spectrum on the left was acquired on resonance and phased for pure absorption. Successive spectra were acquired at 2500 Hz increments from resonance, and the same phase correction was used. The $\frac{1}{2}\pi$ pulse in this case was set to 40 μ s, corresponding to a precession rate of 6250 Hz around the rf magnetic field. The dashed vertical line is at this value

$\gamma B_1 = 25$ kHz, and it is not unusual for a line in the spectrum of a heavy element at high magnetic field to be 25 kHz off resonance. In such cases, the effective rf field is a long way from the (x, y) plane. However, as Figure 4 shows, the spectrum is remarkably little affected, despite the breakdown of the model of the pulse. The intensity of the line remains large out to offsets of $5\gamma B_1$, and the principal distortion is just the phase of the signal. In some sense, the effective field is self-compensating. As the signal moves off resonance, the effective field is tilted up out of the (x, y) plane, but it gets stronger because of the contribution of the offset from resonance. A flip angle of $\frac{1}{2}\pi$ on resonance becomes a flip angle of $\sqrt{\frac{1}{2}}\pi$ about an effective field that is tilted up by an angle of 45° . The net xy component of the magnetization has a similar magnitude in each case, but the phase is different.¹¹

In order to achieve some sort of selective excitation, pulses are often deliberately made long and weak (see *Shaped Pulses* and *Selective Pulses*). There is a temptation to think of the excitation profile of a pulse as the Fourier transform of the pulse shape, but this can be very dangerous. Because of the coherence in the system, the detailed response to a weak pulse must be calculated using density matrix treatments.

Off-resonance effects can be removed very efficiently by the use of sequences of pulses that correct for some of the inaccuracies (see *Composite Pulses*). These are sequences of pulses with different phases, which can dramatically extend or shape the frequency response of the sequence. The design of these pulse sequences is quite sophisticated, and depends on the exact application. For instance, a sequence $(\frac{1}{2}\pi)_x - (\frac{4}{3}\pi)_y - (\frac{1}{2}\pi)_x$ is very good at taking z magnetization

and inverting it, but it is not the best sequence for reversing an xy magnetization to create a spin echo.

4.4 Pulsed Spin Decoupling

For many nuclei, such as ^{13}C , it is convenient to remove proton couplings from the spectrum so that there is a single line for each carbon site in the molecule. Originally this was done with strong CW irradiation (see *Double Resonance*) or with digital noise modulated rf. The aim is to quantize the protons perpendicular to the direction of the carbon quantization, so that the scalar coupling (which is the scalar product of the proton and carbon vectors) vanishes. Because of off-resonance effects, this works only over a narrow range.

Subjecting the spin to a continuous sequence of pulses works much better (see *Decoupling Methods*). Several sequences have been developed, with acronyms such as MLEV, WALTZ, and GARP, based on the concepts of composite pulses and refocusing of errors. These provide much better decoupling over a wider range of parameters, and are now standard practice.

4.5 Pulses Acting on Quadrupolar Systems

For a single spin- $\frac{1}{2}$, there is a rigorous and very useful mapping between the observable magnetizations and the components of a vector. For quadrupolar nuclei, those with spin quantum numbers greater than $\frac{1}{2}$, the situation is much more complex, particularly in solids and other rigid systems.

For these nuclei, the interaction of the magnetic quadrupole with the electric field gradient must be considered (see *Quadrupolar Interactions*). This interaction varies, depending on local symmetry at the nucleus, but it may be tens of megahertz. Therefore, the assumption that the rf field dominates all the interactions no longer holds. However, there are some limiting cases in which the interaction of the nucleus and the rf field can be made relatively simple.

The first case is that in which the quadrupolar interaction is relatively weak. This can occur when the electric field gradient is small, as in symmetric environments, or the quadrupole moment itself is small, as in ^6Li or ^{133}Cs . A very important example is the deuterium nucleus in a C–D bonded system, for which the quadrupolar interaction is approximately 150 kHz. For this case, a pulse is still equivalent to a rotation of the frame of reference, and the angular momentum methods used for spin- $\frac{1}{2}$ systems work very well.¹² However, the results are not as intuitively obvious as in the spin- $\frac{1}{2}$ case. For a spin-1 nucleus like deuterium, the echo sequence used is not the $\frac{1}{2}\pi - \pi$ Hahn echo sequence, in which the rf phases are not critical. Rather, the $(\frac{1}{2}\pi)_x - (\frac{1}{2}\pi)_y$ sequence is used, which is based on the solid echo sequence. For nuclei with larger spin quantum numbers, there may not even be a good echo sequence. Still, the basic principles of how a pulse affects a system with a small quadrupolar coupling are well-established.

When the quadrupolar interaction is large, there is no general solution. Angular momentum methods are not so useful, since a pulse is no longer equivalent to a rotation of the frame of reference. In many cases, numerical computations are necessary, and the results are difficult to interpret. An example of this is nutation spectroscopy, in which we look at the

response of a system to a pulse of regularly increasing length (see *Nutation Spectroscopy of Quadrupolar Nuclei*). Some analytical results for spins $\frac{3}{2}$ and $\frac{5}{2}$ have been published,¹³ but the general problem is still unsolved.

One case that can be analyzed is that of systems with half-integral spins and strong quadrupolar coupling. For these systems, most of the transitions are very broad and unobservable, but the $-\frac{1}{2} \rightarrow +\frac{1}{2}$ is not affected to first order by the quadrupolar coupling, and remains relatively sharp. This transition can be treated as a two-level system, using the fictitious spin- $\frac{1}{2}$ method. For this central line in a spin- I system, the rf pulse acts in the normal way, but the effective flip angle for a pulse is $\alpha(I + \frac{1}{2})$, rather than α .¹⁴ This has the consequence that small flip angles ($\frac{1}{10}\pi$) are needed to get good quantitative spectra of quadrupolar nuclei such as ^{27}Al (see *High Speed MAS of Half-Integer Quadrupolar Nuclei in Solids*).

5 CONCLUSIONS

The response of spins to rf fields is central to NMR. Modern pulse NMR consists in using combinations of pulses and delays to manipulate spin systems. The behavior during a delay is more familiar, since we observe this directly in an FID. What happens during a pulse is much less obvious.

The basics are very simple, but capable of provoking almost endless fascination. In most cases, the pulse is equivalent to a rotation of the frame of reference—but this is not necessarily equivalent to a rotation of a magnetization vector in the laboratory frame. What happens in detail to a coupled spin system during this rotation requires a mathematical description, usually based on angular momentum properties of the system. This combination of experiments, theory, simulations, experience, and educated intuition is needed to understand the response of nuclear spin systems to radiofrequency pulses.

1 INTRODUCTION

This article introduces nuclear spin relaxation primarily in the *weak limit*, by which we mean the kind of relaxation theory that is also called the perturbation limit, or the motionally narrowed limit. This is the most common form of relaxation in NMR.

Generally any theoretical treatment of relaxation divides the equations of motion of the spin system into two parts: first, a static or nearly static part consisting of the Zeeman energy, the spin–spin couplings (usually also including the dipolar energy between spins, and quadrupolar interactions, for rigid solids), and some other terms depending on the system; and second, a randomly time-varying part that produces relaxation. The latter can often be described approximately by two parameters: a size in energy units of $\hbar\omega_i$, and a time τ_c or ‘correlation time’, which is a characteristic time, usually the time that it takes for the random interaction to change by an amount that is unpredictable but is comparable to $\hbar\omega_i$. For example, when two nuclear spins in a molecule in solution relax mainly via the dipolar interaction between each other, ω_i is of the order of 10^5 s^{-1} for vicinal protons, decreasing as the inverse cube of the distance for further neighbors, and τ_c is of the order of the time for the interspin vector to rotationally diffuse by about one radian away from any initial direction. Neither ω_i nor τ_c can be defined precisely for every problem, although for some important problems they can be usefully defined. For large biopolymers, τ_c is of the order of 10^{-8} s , and it is roughly proportional to molecular weight.

The weak limit is almost always valid if $\omega_i\tau_c \ll 1$, but a more useful criterion is that the relaxation rate (such as T_1^{-1} or T_2^{-1}), calculated using the weak limit formulas, be small compared to ω_i . A useful rule of thumb is that transverse relaxation times T_2 are of the order of $\omega_i^2\tau_c$ and longitudinal rates are of the order of $\omega_i^2\tau_c/(1 + \omega^2\tau_c^2)$, where ω is a nuclear

spin frequency, or difference in nuclear spin frequencies, depending on the relaxation process under consideration. It is commonplace that $\omega\tau_c$ be greater than one for moderately large molecules, and it also can happen that $\omega_i\tau_c$ is greater than one, so that T_2 processes cannot be treated using the weak limit, whereas, in the same system, T_1 processes can be. In fact, T_1 processes can almost always be treated by the weak limit, with the exception of experiments, usually field cycling, performed at low field; and for conceptually similar experiments in the rotating frame such as studies of slow motions described in *Ultraslow Motions in Solids*.

In the present article, we shall introduce this topic in as simple a way as possible, in the hope of demystifying it for the inexperienced reader. We do not attempt a thorough review or much discussion of the different classes of relaxation that can occur. Even setting up the main Hamiltonian and the smaller time-dependent Hamiltonian requires many assumptions and some intuition about the system. On the other hand, we shall mention a number of topics not found in general texts. We shall not discuss details of applications since these are treated elsewhere in this Encyclopedia. Fortunately, the list of relaxation interactions is not long: dipolar relaxation already mentioned; similar relaxation due to electron spin–nuclear spin interaction in paramagnetic materials; spin–rotation interaction, especially in gases but also in smaller molecules in solution; and, for nuclei other than spin- $\frac{1}{2}$, the fluctuating electric quadrupolar interaction.

The kind of theory we have been describing is called *semiclassical*, because the time dependence of the perturbing interaction is generally described by classical variables such as distances. Relaxation theories can be, and generally are, also set up completely quantum mechanically. Unfortunately, the character of the time dependences of most relaxation interactions cannot be calculated from first principles, so that most relaxation theories are semiclassical. An exception is relaxation by lattice vibrations in solids or electron spins in metals, although even in these cases theories are likely to be somewhat phenomenological. Quantum relaxation theory also helps to justify some apparently arbitrary assumptions of the semiclassical theory.

2 REVIEW OF THE LITERATURE

The original Bloch equations,¹ containing two relaxation times, hinted at the probable richness of information contained in relaxation theory. T_1^{-1} was the rate at which energy changes would occur, and this more demanding process was expected to be slower than T_2 (line-broadening) processes, which do not require energy transfer in the absence of an rf field. The basic picture of nuclear relaxation was virtually completed with the masterful paper by Bloembergen, Purcell, and Pound (BPP), connecting transition rates between levels with spectral densities, and T_2 processes primarily with spectral densities at zero frequency.² By symmetry, T_1 and T_2 should be equal in the low-field limit and also, since T_2 must be a continuous function of B_0 , $T_1 = T_2$ in the limit of short correlation time, $\omega_0\tau_c \ll 1$ (where ω_0 is the Zeeman frequency γB_0).

In early papers, it was assumed that the relaxation by spin–spin interactions in rigid solids would produce straightforward transverse relaxation, but this view was

incorrect. The dipolar spin–spin interaction has to be treated separately from weak relaxation mechanisms in a rigid solid, and it can participate in a wide variety of interesting phenomena.

The next important development was the introduction of the density matrix to describe the system to be relaxed, and the satisfactory calculation of T_1 and T_2 for a single spin, by Wangness and Bloch. This treatment was then restated and generalized by various workers. Kubo and Tomita provided a theory based on the general theory of irreversible processes; Bloch treated relaxation in the rotating frame, among other things; and the present writer provided a version of the theory that may be useful to the novice reader. During this same period, Solomon was performing his important experiments on the HF molecule, providing a systematic basis for discussion of cross-relaxation theory (NOE) as treated in the papers of Solomon and Bloembergen. The topic has been treated in several texts, reviews, and monographs,^{1–15} of which Abragam's may be the most lucid introduction to the operator version of the formalism.^{3,6,14} In the present article, we use the notation of our own work¹⁵ and of Slichter⁴ as far as possible, while maintaining consistency with the other articles in this Encyclopedia. Excellent reviews of applications of weak and strong relaxation theories can be found in the books edited by Muus and Atkins⁸ and by Tycko.¹¹

A somewhat separate, more sophisticated and general approach has been developed by several theorists, based primarily on the work of Kubo and Tomita, and of Morita.^{8,10,12,13} The reader should be aware that there is only one underlying theory, and that the independent formalisms of various workers mentioned are all valid, and differ only in sophistication and in suitability for different problems.

3 STRONG RELAXATION

Strong relaxation theories are not presented here, but we describe them briefly. Many such theories are generalizations of the early well-known treatment of McConnell and of Slichter in which the chemical shift of a single spin is assumed to change at a random rate between two definite values, as a model for a dynamic change between two major average conformations. Generally, weak mechanisms such as dipolar relaxation are grafted onto such a theory, and the entire spin-dynamic problem can be solved analytically, as described in *Chemical Exchange Effects on Spectra*. Sometimes essentially the same kind of theory is set up with an infinite number of conformational states and shifts. An important example is the simulation of lineshapes for deuterium NMR in membranes and liquid crystals. The type of problem discussed in *Ultraslow Motions in Solids* is also in this class.

All such strong relaxation mechanisms can become weak in the limit where the correlation time becomes sufficiently short, as already implied.

Another class of strong relaxation mechanisms is that of the Orbach processes, in which excited electronic states are important.⁸ This type of relaxation is not important for NMR problems, except perhaps for paramagnetic solids.

Finally we mention Anderson theory,⁸ which was first used to describe the exchange narrowing³ of electron spin resonances in solids. In NMR, it is adapted to estimate

linewidths of dilute heteronuclei in solids,³ and processes like solid state cross relaxation and magnetization (spin) diffusion for which perturbation theory is not applicable, but that are nevertheless slow.⁷

4 ENSEMBLES, SYSTEMS, OPERATORS, AND REPRESENTATIONS

We now describe the elements of models for relaxation theories. Here and throughout this article we only outline those topics that are relatively standard. The reader who is not familiar with topics mentioned is urged to refer to the literature surveyed above and to standard texts on quantum and statistical physics.

A typical relaxation theory treats the average behavior of an *ensemble* of systems. Most generally, each member of the ensemble is a replica of the NMR lab, according to Gibbs, but an almost equivalent view is that each member of the ensemble is represented by a single experiment on the same system, out of a large ensemble of experiments in which the sample is prepared as far as possible in the same way each time. A gentler version of an ensemble can be that it represents the average behavior of many pieces of a large sample of N particles ($N \approx 10^{23}$), each piece having fewer than N particles, but still a great many, say 10^{12} . Finally, it is useful sometimes, though not strictly correct, to view each member of the ensemble as one molecule out of the collection (ensemble) of molecules being studied. The latter view cannot be used for a rigorous treatment of intermolecular or collective effects such as intermolecular NOE or 'radiation damping'. In any case, it is most important to be entirely clear as to what system one is defining, before starting.

As already indicated, a starting point for any semiclassical weak relaxation theory is to write the Hamiltonian $\hat{\mathcal{H}}$ in the form

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_0 + \hat{K}(t) \quad (1)$$

where $\hat{\mathcal{H}}_0$ is the main Hamiltonian, and relaxation is produced by the randomly varying part $\hat{K}$. It is specifically assumed that $\hat{K}$ has zero value after being averaged over the ensemble: $\langle \hat{K}(t) \rangle = 0$, where the angular brackets always denote the ensemble average. It is important to remember that $\hat{K}$ is assumed to be different for each member of the ensemble.

It is useful to note explicitly that $\hat{K}$ can usually be written as the sum of more or less independent terms, each of which can be written (for one member of the ensemble) as a spin operator times a function of classical variables (usually internuclear distances, and angles defining directions of internuclear vectors):

$$\hat{K} = \sum_q H_q(t) \hat{K}^q \quad (2)$$

The H_q are ordinary real random functions of the time. They can be terms such as those of the dipolar interaction of BPP, for example $\hbar^2 \gamma^2 (1 - 3 \cos^2 \theta)/r^3$. The $\hat{K}^q$ s corresponding to this H_q would be the operators $\hat{I}_{1z} \hat{I}_{2z}$ and $-\frac{1}{4}(\hat{I}_1^- \hat{I}_2^+ + \hat{I}_2^+ \hat{I}_1^-)$. In this case, the classical variable H_q is random because θ and

r vary randomly, in solution. The elements of $\hat{K}^a$ may also be functions of the time for a time-dependent *representation* of the system, discussed below. For weak relaxation, it turns out that all we need to know about $\hat{K}$ are the auto- and cross-correlation of the functions $\langle H_q(t)H_{q'}(t + \tau) \rangle$. These will be discussed later.

The quantum Hamiltonian is an operator, and the thing on which it operates is a wavefunction:

$$\psi = c_n(t)u_n \quad (3)$$

where the c_n are complex numbers that generally vary with time, and the u_n are a complete set of *basis functions*. There are rules concerning how to set up such a complete set, and how they must change under transformations of various kinds. For spin problems, we mention four, out of many, ways to define them.

1. The u_n can be wavefunctions that specify the orientation (or m_z , for $S > \frac{1}{2}$) of each spin in the system. These are eigenfunctions of the Zeeman Hamiltonian and we call this the ‘Zeeman’ representation.
2. The u_n can be eigenfunctions of the entire main Hamiltonian $\hat{H}_0$, with energy eigenvalues E_n . $\hat{H}_0$ includes, in addition to the Zeeman Hamiltonian, spin–spin coupling for molecules in solution. Deriving these u_n from the Zeeman ones can be easy—or it can be very complicated—but nevertheless it is useful to talk about them. This is the ‘Schrödinger’ representation. The terms c_n generally depend on time in this representation, as $\exp(iE_nt/\hbar)$, modified by relaxation.
3. The u_n can be appropriate for a rotating frame transformation. For such a transformation, most of the Zeeman Hamiltonian is removed, and the u_n are the same as for case 1 except that the new u_n are equal to those of case 1 multiplied by $\exp(-i\omega_j t)$, where ω_j are the sums of, or differences between, nuclear resonance frequencies of relevant spins. This could be called the ‘product operator’ representation, since it is used for product operator theory.
4. The representation may be one in which the entire average Hamiltonian $\hat{H}_0$ is transformed away. This is the ‘Heisenberg’ or ‘interaction’ representation. It is most convenient for setting up relaxation theory. In this representation, the c_n are time-independent except for the relaxing effect of $\hat{K}(t)$, and the new u_n are equal to those of the Schrödinger representation times $\exp(-iE_nt/\hbar)$. All operators such as $\hat{K}(t)$ are similar to their form in the Schrödinger representation, except that their off-diagonal elements are time-dependent.

The wavefunction ψ is completely specified by specifying the basis u_n and all the c_n . The latter set of numbers is viewed as a *vector in Hilbert space* in analogy to the set (x, y, z) of coordinates that represents the real-space position vector of a particle.

Before proceeding, we note that $\hat{H}_0$ can include time-varying things such as rf pulses or field gradients. For the most part, we ignore such fields. Equation (1) also omits any semiclassical interaction that restores thermal equilibrium. The equation should include another friction term that will do so.^{8,13,16} Otherwise, the energy of each system will increase continuously, toward infinite temperature. This is a consequence of the fact that $\hat{K}(T)$ does not have a temperature associated with it.

In fact, *nuclear spin relaxation theory is virtually identical to Brownian motion theory*. It deals with Brownian-like motion of vectors, in Hilbert space, that describe the spin system.^{8,10} In each time of the order of the correlation time τ_c , an individual system wavefunction changes very little, in analogy to the effect of single collisions on a large particle undergoing Brownian motion. The interested reader should read the last chapter of Reif’s text¹⁷ to see how Brownian motion of relatively large particles is related to fluctuating forces of the surrounding medium—in particular to the spectral densities (see below) of these forces. The analogy to Brownian motion may reassure the novice reader that nuclear spin relaxation involves nothing really new. In particular, Brownian motion theory always contains a presumed force of friction, and Einstein showed how the friction coefficient must be related to the diffusion coefficient, which is a manifestation of the fluctuating forces of collisions. Frictional forces were not described as such in early papers.^{15,16}

The statement in the above paragraph describes an *analogy*, which should not be confused with the important *applications* of NMR to the study of real diffusion. These include studies of translational diffusion, dating back to Hahn’s original papers on spin echoes, and of rotational diffusion, starting with BPP (reviewed, for example, in *Relaxation Effects of Chemical Exchange*).

5 THE DENSITY MATRIX AND THE RELAXATION MATRIX

The density matrix is defined by⁴

$$\sigma_{ij} = \langle c_i c_j^* \rangle \quad (4)$$

where $*$ here denotes the complex conjugate. Notice that it is a matrix whose elements depend on what representation we are using, which has to be kept in mind during any discussion or calculation. The density matrix can be shown to transform in the same way as any standard quantum operator, under change of representation, so it can be thought of as an object $\hat{\sigma}$ that is represented in some particular representation by a matrix σ_{ij} . Thus $\hat{\sigma}$ is often referred to as the density operator, even though it does not seem to operate on anything.

The symbol $\hat{\rho}$ was originally used for the density matrix of an entire system, including coordinates of nonspin variables. The notation $\hat{\sigma}$ was introduced to denote a “reduced” density matrix that describes the nuclear spin system alone. Often, as for example in the product operator formalism, $\hat{\sigma}$ is written as a sum of products of spin operators; this is what we mean by an operator formalism. Use of this language implies that correlations between spin orientations and molecule or lattice variables are, on the average, not large. This assumption has to be dropped for strong relaxation theories. In the absence of relaxation, $\hat{\sigma}$ obeys the quantum version of the Liouville equation:

$$\frac{d\hat{\sigma}}{dt} = \frac{i}{\hbar} [\hat{\sigma}, \hat{H}_0] \quad (5a)$$

where $[\hat{\sigma}, \hat{H}_0]$ denotes the commutator bracket $\hat{\sigma}\hat{H}_0 - \hat{H}_0\hat{\sigma}$.

The Schrödinger representation that we will use is not convenient for actual calculations, but is useful in developing and discussing the general theory. In this representation, the basis functions u_n are exact eigenvalues of $\hat{\mathcal{H}}_0$, as already mentioned. The diagonal element σ_{ii} of $\hat{\sigma}$ is simply the probability that the energy level E_i is occupied. As expected, the Liouville equation predicts that σ_{ii} will be time-independent, a consequence of the fact that $\hat{\mathcal{H}}_0$ is diagonal in this representation. The elements of $\hat{\sigma}$ represent the entire set of possible physical observables of the system. These are not the same things that we may observe in practice, and in NMR there is usually really only one quantity that we observe. It is the transverse magnetization in the fixed x direction, $\hat{M}_x$. Its expectation value is given by $\text{Tr}(\hat{M}_x \hat{\sigma})$, where Tr means a sum over diagonal elements. It is the sum of many off-diagonal elements of $\hat{\sigma}$ in the Schrödinger representation, because $\hat{M}_x$ has many off-diagonal elements in this representation, for a system of several spins. From the Liouville equation, the time dependence of an off-diagonal element σ_{ij} is given by a constant times $\exp[i(\omega_i - \omega_j)t]$. Each spectral line in a directly observed spectrum is a manifestation of a coherence represented by an off-diagonal density matrix element, damped, of course, by relaxation not included in equation (5a). However, typically $\hat{\sigma}$ has many more off-diagonal elements than are observed in this way; for a system of 10 protons, for example, it has only 1024 diagonal elements, but roughly a million off-diagonal elements. The vast majority of the latter are both uninteresting and difficult to study. Elements that are not directly observable in a simple free induction decay are called forbidden, and of these the most useful are the lower order (zero, double, triple, etc.) ‘multiple quantum’ coherences.⁶

As might be expected, the result of weak relaxation theory is an equation for $\hat{\sigma}$ that is a direct generalization of Bloch’s equations:

$$\frac{d\hat{\sigma}}{dt} = \frac{i}{\hbar}[\hat{\sigma}, \hat{\mathcal{H}}_0] + \hat{R}(\hat{\sigma} - \hat{\sigma}^0) \quad (5b)$$

where $\hat{\sigma}^0$ is the thermal equilibrium value of $\hat{\sigma}$, equal to a constant times $(\exp -\hat{\mathcal{H}}_0/RT)$. The extra term $\hat{R}(\hat{\sigma} - \hat{\sigma}^0)$ is shorthand for a matrix whose ij element is $\sum_{i'j'} R_{ij'j'}(\sigma_{i'j'} - \sigma_{i'j'}^0)$; thus the *relaxation matrix* $\hat{R}$ is a fourth-order matrix. We shall discuss it using the Schrödinger representation here. The elements of $\hat{\sigma}$ are analogous to the magnetizations in Bloch’s equations, and the term $i[\hat{\sigma}, \hat{\mathcal{H}}_0]/\hbar$ is analogous to $\gamma(\mathbf{B} \times \mathbf{H})$. The coefficients in $\hat{R}$ are extensions of Bloch’s rates T_1^{-1} and T_2^{-1} , and the term $\hat{\sigma}^0$ is similar to his M_0 .

As already mentioned, frictional forces must exist that return the system to equilibrium, and the term $-\hat{R}\hat{\sigma}^0$ was arbitrarily inserted to account for these. As included in equation (5b), it ensures that $d\hat{\sigma}/dt$ is zero at equilibrium, when $\hat{\sigma} = \hat{\sigma}^0$. Friction forces are connected with the memory of the surroundings: for example, as a spin precesses in matter, the interaction represented as relaxation by $\hat{\mathcal{H}}_1(t)$ will slightly deform the matter to produce a small local field at the spin. The deformation is analogous to the deformation in a bed when you lie on it. As the spin moves, this deformation follows it, but not instantly. There is a small lag, and this produces a memory field that is exactly right to make the system approach equilibrium.⁸ The $\hat{R}\hat{\sigma}^0$ term can also be fully justified by

a quantum derivation,¹⁶ or by taking spin interaction into account for the lattice’s motion.¹⁷

6 TRANSITION RATES

The semidiagonal element R_{ijj} is simply the rate constant for the transition from level i to level j . The theory of these transition rates was already fully implied in BPP, not requiring a density matrix for its description. Thus we can redefine σ_{ij} as a probability p_i that level i is occupied, and R_{ijj} as a transition rate w_{ij} from level j to i , writing equations of the form

$$\frac{dp_i}{dt} = \sum_j w_{ij}(p_j - p_j^0) \quad (6a)$$

where p_j^0 is the thermal equilibrium value of p_j , proportional to $\exp(-E_j/kT)$. The form of equation (6a) is based on the relaxation equation, equation (5b), and the w_{ij} are symmetric: $w_{ij} = w_{ji}$, as defined in the original theory.¹⁵ The w_{ij} are not identical to what are normally considered transition probabilities, which occur in the so-called master equation:

$$\frac{dp_i}{dt} = \sum_j (W_{ij}p_j - W_{ji}p_i) \quad (6b)$$

Here, detailed balance requires $W_{ij}/W_{ji} = \exp[-(E_i - E_j)/kT]$. Equation (6b) is also the equation for standard first-order chemical kinetics, if p_i is replaced by the molarity $[i]$ of systems in spin level i , and the W_{ij} are replaced with first-order rate constants usually denoted by k_{ij} or the equivalent.

Since the matrix w_{ij} is symmetric, whereas W_{ij} is not, equation (6a) is inconsistent with the more general equation, equation (6b), and with detailed balance. Apparently, the convenient form of relaxation theory described by equation (6a) is valid only in the high-temperature approximation, where $(E_i - E_j)/kT \ll 1$. Fortunately, this approximation is almost always obeyed for NMR experiments. In that case, it is reasonable to specify W_{ij} by

$$W_{ij} = w_{ij} \left(1 - \frac{E_i - E_j}{2kT}\right) \quad (7)$$

which preserves detailed balance within the high-temperature approximation. The problem with the semiclassical theory mentioned above can be avoided, when the high-temperature approximation is invalid, by either using the completely quantum version of the theory,¹⁵ or by augmenting the semiclassical model of equation (1) with a memory, or friction term, as already mentioned.^{13,16} A simple example of a memory effect is ‘radiation damping’ (see below).

For a large and important class of experiments such as NOESY, the situation is even simpler. With important exceptions such as methyl groups, there are no complicated correlations between spins, and the important evolution by relaxation is described by diffusion of magnetization among spins (‘spin diffusion’). Relaxation is described by

$$\frac{dm_i}{dt} = \sum_j s_{ij}(m_j - m_j^0) - r_1(m_i - m_i^0) \quad (6c)$$

where m_i is the z component of magnetization of the i th spin species, m_i^0 is its thermal equilibrium value, r_i is the relaxation rate of the i th spin due to all mechanisms, and the s_{ij} are cross relaxation rates between spins. Note that s and r are often denoted by σ and ρ in the literature. Furthermore, the term ‘relaxation matrix’ is often used in the literature of these problems, to denote the collection of relaxation rates; it is not to be confused with the more complicated $\hat{R}$ matrix of the full theory.

An equation similar to equation (6c) can also describe the ROESY experiment, with redefinition of m_i as magnetization along the effective field of spin i . We shall briefly return to ROESY below.

All these versions of NMR kinetic theory are described by first-order differential equations, whose evolution can be described by sums of simple normal modes, each having a single relaxation time. These modes include in principle all the m_i (or possibly σ_{ii}) and are time consuming to calculate. Magnetization diffusion and relaxation viewed in terms of normal modes has been applied by T. L. James to macromolecules. However, an equivalent approach is to ask how a localized departure from equilibrium, at a single spin i , spreads to other spins as time passes. This ‘Green’s function’ approach is perhaps more economical in computer time than the normal mode approach, and it may provide a rather direct and more intuitive model for the evolution of diagonal and cross peaks in NOESY and ROESY. Routines that can perform such a calculation are included in some NMR data analysis programs. The normal mode approach is more useful for problems having a high degree of symmetry.

7 LINEWIDTHS AND OFF-DIAGONAL ELEMENTS

In the Schrödinger representation, any element of σ_{ij} of $\hat{\sigma}$ varies as $\exp(i\omega_{ij}t)$, neglecting relaxation, where $\omega_{ij} = (E_i - E_j)/\hbar$. The elements of $\hat{R}$ are time-independent (only for this representation!). A *secular* term $R_{ii'jj'}$ is one for which $\omega_{ii'} = \omega_{jj'}$. All the rates in the previous section are thus secular, because all the ω_{ii} and ω_{jj} are zero. Likewise, terms of the relaxation matrix $\hat{R}$ terms R_{ijij} , which are rather direct analogs to Bloch’s rate T_2^{-1} , are secular. The minimum full linewidth of a spectral transition between levels i and j is R_{ijij}/π , just as the full linewidth for Bloch’s equations is $(\pi T_2)^{-1}$. Thus, if all relaxation terms of equation (5b) are ignored except R_{ijij} then σ_{ij} varies as a damped exponential, $\exp(i\omega_{ij}t + R_{ijij}t)$. The sign of R_{ijij} is negative (see below).

Those terms of the relaxation matrix $\hat{R}$ that are not of the form R_{ijij} or R_{ijij} can mostly be ignored. That is fortunate, because $\hat{R}$ has roughly 10^{12} elements for a 10-proton problem, for example.

Specifically, any element $R_{ii'jj'}$ connecting any density matrix element $\sigma_{ii'}$ to another one $\sigma_{jj'}$ can often be ignored provided

$$|\omega_{ii'} - \omega_{jj'}| |R_{ii'jj'}| \gg 0 \quad (8)$$

If equation (8) is strongly obeyed (if the equation is valid with $>$ replaced by $\gg$) then the element of $\hat{R}$ being considered is a time-independent relaxation term connecting two elements of $\hat{\sigma}$ that are varying rapidly compared with the element of $\hat{R}$.

These terms are called ‘nonsecular’, and they are expected to perturb the final solution by an amount equal to the ratio of the right-hand to the left-hand side of equation (8), compared with secular terms of the same size. The name and idea of secular and nonsecular perturbations date back to classical mechanics, and were invoked by Van Vleck in truncating the dipolar Hamiltonian in order to calculate moments of resonance lines.

Terms in $\hat{R}$ for which equation (8) is only weakly obeyed, or corresponding terms in operator-based theories of relaxation,¹⁴ should always be included in any solution of a relaxation problem. The effect of such terms can be dramatic, and can unexpectedly produce narrowing, and collapse of multiplets. A simple example is the non-observance of ^{14}N splitting of the proton resonances of NH groups, due to rapid electric quadrupole relaxation of the ^{14}N spin. The N–H J splitting is suppressed by rapid relaxation coupling of coherences of the product operator form $\hat{I}_z \hat{S}_x$, where I is ^{14}N and S is the NH proton. Of course, this example, like many, does not require density matrix relaxation theory in order to be understood. This kind of relaxation is called ‘narrowing of the second kind’.³

8 EFFECTS OF RF FIELDS: SPIN LOCKING

The consideration of nonsecular terms in $\hat{R}$ became richer when it was realized that the elements of $\hat{\sigma}$ can have their time dependence altered by the presence of rf fields, such as in a spin lock experiment. Off-diagonal elements can be driven to have periodic variation at the rf frequency, rather than their natural frequencies, and elements of $\hat{R}$ that connect two elements of σ which have slightly different frequencies become secular. Thus, rf fields can alter the relaxation behavior, as first shown by Vold and Vold. Here it is assumed that $\hat{R}$ itself is not affected by the rf field. A commonplace example of this effect is in the ROESY (CAMELSPIN) experiment of Bothner-By. Magnetizations of different spins cross relax in this experiment because they are spin locked at the same rf frequency, and these magnetizations correspond directly to off-diagonal density matrix elements that would evolve at different frequencies, and not cross relax, in the absence of the spin lock. It must be emphasized, however, that the ROESY experiment was undoubtedly invented and analyzed independently of the theory outlined in the present article.

The phenomena described in the last paragraph are quite general. Another useful measurement can be made on systems that are expected to have dynamic, chemical, or conformational changes taking place on a timescale in the range of 10 ms or slower. Then it is of interest to study the variation in the transverse relaxation time with respect to the spin-locking rf field intensity $\omega_1 = \gamma B_1$. This relaxation time is generally called $T_{1\rho}$, since the process it describes resembles a T_1 process, but in the rotating frame. The theory of $T_{1\rho}$ can be treated using spectral densities and density matrix theory, following Bloch, or it can with equal validity be treated using the type of theory reviewed in *Chemical Exchange Effects on Spectra*. In general, $T_{1\rho}$ starts to decrease below its value at zero B_1 , (which is the same quantity as T_2) at field intensities where $\omega_1 \tau_c$ approaches one. Here τ_c is the correlation time for the slow perturbation. Such a measurement yields an estimate of this correlation time, and also the general size of the shift ω_i associated with the perturbation.

9 CROSS-CORRELATION EFFECTS

An understanding of the effect of cross correlations between the random functions $H^q(t)$ in equation (2) can help to provide interesting information about a system from its linewidths or transition rates. This topic is reviewed in *Relaxation Processes: Cross Correlation and Interference Terms*. An important example is the often-seen unequal linewidth of ^{13}C (or ^{15}N) multiplets, due to correlation and interference between the dipolar interaction and the CSA of the ^{13}C nucleus. A rough estimate of the CSA can be obtained from this effect.⁵

To understand the general usefulness of cross-correlation effects, consider the dipolar interaction in a hypothetical spin system ABC, where nuclei A, B, and C are nonequivalent protons and the distances A to B, and B to C, are assumed fixed and equal. If the angle ABC could vary randomly with equal probability for all angles then the spectrum of B would show an uninteresting multiplet due to the uncorrelated dipolar interactions between A and B, and B and C. If, instead, the system is rigid and linear, with the angle ABC equal to 180° , the dipolar interactions mentioned above are highly correlated. If spins A and C are oriented oppositely for the rigid linear case, their dipole fields at B will cancel; if spins A and C are both oriented in the same direction, the dipolar fields always add. Thus, the centerlines of B's multiplet will be narrow, and the outer lines will be four times as broad as in the uncorrelated case.

An interesting example of a correlation effect is 'radiation damping'. This is due to the rf fields, fluctuating and induced, from the probe pickup coil. The effect is misnamed, because no radiation is involved. It is a correlated effect, because the field felt at each spin is virtually the same as at every other spin. This means that these fields cannot directly change the magnitude of total nuclear magnetism, only its direction, if rf inhomogeneity of the probe coil is ignored.

10 TRANSVERSE RELAXATION RATES AND DYNAMIC SHIFTS

Let us focus on two levels i and j giving an observable signal, or a forbidden coherence, at a frequency $\omega_{ij} = (E_i - E_j)/\hbar$, where E_i and E_j are the energies of the two levels. We shall not write down the form for the elements of $\hat{R}$ in general, which can be found in many texts, as well as in other articles in this Encyclopedia. However, it is of interest to write the expressions for elements of $\hat{R}$ that are most closely analogous to Bloch's relaxation rates as explained above. The term similar to T_1^{-1} is R_{iijj} , given by

$$\frac{1}{2} T_1^{-1} R_{iijj} = J_{ijij}(\omega_{ij}) + J_{jiji}(\omega_{ji}) \quad (9a)$$

Here T_1^{-1} is the apparent rate that would be measured for the spectral line at ω_{ij} by a selective saturation-recovery experiment, and '>' indicates that the actual apparent rate could be shortened by relaxation to levels other than i and j . The factor of $\frac{1}{2}$ multiplying T_1^{-1} is inserted because Bloch's T_1^{-1} is twice the rate constant connecting two levels in a two-level master equation, as one can verify by writing and solving such a master equation for the recovery of M_z . The

J s are Fourier transforms of correlation functions of $\hat{K}$. They are called spectral densities, and are given in general by

$$J_{ijj'j'}(\omega) = \int_{-\infty}^{\infty} e^{i\omega\tau} \langle K_{ij}(t) K_{i'j'}^*(t + \tau) \rangle d\tau \quad (10)$$

with * here denoting the complex conjugate. The expressions within the ensemble-average brackets $\langle \rangle$ are cross-correlation functions, or autocorrelation functions if $i', j' = i, j$. These are assumed to be real and independent of t , and are also assumed to be even functions of τ (that is, unchanged by the substitution of τ by $-\tau$). From these assumptions, it is easy to show that the right-hand side of equation (9a) is real, as it has to be.

The term of $\hat{R}$ most closely similar to Bloch's T_2^{-1} is

$$\begin{aligned} T_2^{-1} R_{ijij} &= 2J_{iijj}(0) - J_{iiii}(0) - J_{jjjj}(0) \\ &\quad - J_{ijij}(\omega_{ji}) - J_{jiji}(\omega_{ji}) \\ &\quad - \sum_{m \neq i, j} [J_{mimi}(\omega_{mi}) + J_{mjmj}(\omega_{mj})] \end{aligned} \quad (9b)$$

This equation is much simpler than it appears, and can be obtained from the original equations for the $\hat{R}$ matrix given elsewhere⁶ and in *Dynamic Frequency Shift; Relaxation Processes: Cross Correlation and Interference Terms and Relaxation Theory for Quadrupolar Nuclei* by rearranging sums, and substitution of equation (9a).

The first three terms on the right-hand side of equation (9b) can be rewritten [by substitution with equation (10)] as

$$\begin{aligned} &2J_{iijj}(0) - J_{iiii}(0) - J_{jjjj}(0) \\ &= - \int_{-\infty}^{\infty} \langle \Delta_{ij}(t) \Delta_{ij}(t + \tau) \rangle d\tau \end{aligned} \quad (11)$$

where $\Delta_{ij}(t) = K_{ii}(t) - K_{jj}(t)$. The quantity Δ_{ij} is just the fluctuating part of the first-order extra splitting between levels i and j produced by the perturbation $\hat{K}(t)$ for a member of the ensemble, and equation (11) is the zero-frequency spectral density associated with this fluctuation, or its 'motionally averaged' relaxation rate. This *adiabatic* term usually dominates relaxation in large molecules. Equation (11) also provides an important refinement over the rule of thumb above that transverse relaxation rates are proportional to $\omega_i^2 \tau_c$, where ω_i^2 is approximately the size of squares of elements of $\hat{K}$. For T_2 processes, it is the size of fluctuating *differences* between diagonal elements of $\hat{K}$ that matters. The adiabatic contribution to T_2^{-1} is often denoted by $(T_2^*)^{-1}$ (here of course, * does not indicate the complex conjugate).

For example, in larger proteins, the dipolar interaction between ^{15}N and H, for NH groups of fully ^{15}N -labeled proteins, might be expected to dominate linewidths. However, for double quantum evolution, as in heteronuclear double quantum correlation experiments, the dominant $\hat{I}_z \hat{S}_z$ part of the dipolar interaction does not contribute to widths, because it affects the two levels connected in the zero, and the double, quantum coherences equally. Thus the double quantum transition connects levels $m_I = m_S = +\frac{1}{2}$ with levels $m_I = m_S = -\frac{1}{2}$, and the expectation value of the operator $\hat{I}_z \hat{S}_z$ is the same for both of these levels. The spacing between these two

levels does not fluctuate as the molecule tumbles, even though the energy of each level fluctuates; they fluctuate together (as far as this particular dominant interaction is concerned). Simple reasoning of this kind is often useful in thinking about linewidths.

The next two terms of equation (9b) are equal, and the sum of their real parts is identical to R_{ijij} [see equation (9a)]. The real part often dominates, and its presence in equation (9b) indicates that T_1 processes will always contribute to T_2 processes. However, comparing with equation (9a), the contribution is only half of the minimum value T_1^{-1} . The origin of the factor $\frac{1}{2}$ can be seen for a model system consisting of a single spin interacting with a fluctuating field $\mathbf{h}(t)$. T_1 processes (longitudinal spin flips) are produced by both of the transverse components of $\mathbf{h}(t)$, namely h_x and h_y . However, transverse relaxation of magnetization M_x , for example, cannot be produced by h_x , only by h_y , because h_x is along M_x . Transverse relaxation can also be produced by h_z , but this latter contribution is the adiabatic kind of relaxation discussed above, represented by the first terms in equation (9b).

The terms of equation (9b) discussed so far are often described in the older literature by the equation $T_2^{-1} = (T_2^*)^{-1} + \frac{1}{2}T_1^{-1}$.

The real part of the last terms expresses the obvious fact that T_1 relaxation to other levels m , in a multispin or $S > \frac{1}{2}$ system, will also contribute to T_2 . However, in contrast to equation (9a), the last five terms of equation (9b) are not arranged in pairs ensuring that their sum is real. In fact, if the magnitudes of ω_{ij} , ω_{jm} or ω_{im} are greater than τ_c , the imaginary parts of these terms can be greater than the real parts, a fact that was not properly recognized in the earlier theories of weak relaxation, and was first emphasized by Paul Hubbard.¹⁵ These imaginary contributions to ' T_2 ' give rise to 'dynamic shifts' of resonances, and are reviewed in *Dynamic Frequency Shift*.

These dynamic shifts are useful for making an estimate of the size of fluctuating parts of $\hat{K}$. They can also be derived quantum mechanically as the second-order perturbation of the spin-lattice interaction, represented above semiclassically by $\hat{K}(t)$, on the spin levels.¹⁵ An important example of a dynamic shift is that of the resonance connecting the $\pm\frac{1}{2}$ levels of a quadrupolar spin, relaxed by a fluctuating electric field gradient. In this case, $\hat{K}$ does not connect these levels directly, and the first terms of equation (9b) are therefore small. The last terms are mainly imaginary provided $\omega_0\tau_c > 1$, where ω_0 is the Larmor frequency.

11 DERIVATION OF THE RELAXATION EQUATION

The general form of the terms of $\hat{R}$ is given in some of the other articles in this Encyclopedia. It is most easily derived in the time-dependent Heisenberg representation mentioned above, in which the time-average main Hamiltonian $\hat{\mathcal{H}}_0$ is transformed to zero, and each element of the perturbation $K_{ij}(t)$ is replaced by $e^{i\omega_{ij}t}K_{ij}(t)$. Lacking the perturbation $\hat{K}(t)$, each ensemble member would have a stationary wavefunction in this representation, and $\hat{\sigma}$ would be time-independent. Relaxation is treated by considering a time Δt that is somewhat larger than any correlation time τ_c , but shorter than any relaxation time. It is always possible to define

such a Δt , by the definition of weak limit relaxation, when that limit applies. One then gets an equation of motion by calculating $\hat{\sigma}(t + \Delta t) - \hat{\sigma}(t)$ using a perturbation expansion, and dividing by Δt to get $d\hat{\sigma}/dt$. The evolution of the c_i is calculated to second order in the elements of $\hat{K}$, for a member of the ensemble. Then the density matrix is formed from the c_i by using equation (4), and terms that are of first order in the $K_{ij}(t)$ vanish because the $K_{ij}(t)$ are zero in the ensemble average. The lowest nonzero terms are the second-order terms, while terms of higher than second order are assumed negligible, and are dropped. Finally, the solution outlined involves double integrals of correlation functions (multiplied by oscillating $e^{i\omega t}$ terms) with limits between t and $t + \Delta t$; these limits are extended to $\pm\infty$ because the integrands are assumed nonzero over only a short range, of the order of τ_c . The mathematics is very simple for secular elements of $\hat{R}$, and the assumptions involved are explained in detail elsewhere.^{4,15} For nonsecular terms, the situation is more complicated; the contribution to the change in $\hat{\sigma}$ for a given time is smaller than it is for secular terms, but this decrease in effectiveness appears to be entirely due to the fact that the elements of $\hat{\sigma}$ in the Schrödinger representation, connected by the elements of $\hat{R}$, have a different time variation. So it was proposed that these elements could be taken to be time-independent in the Schrödinger representation and have essentially the same form as the secular terms. This somewhat unsatisfactory reasoning seems to have withstood the test of time.

The spectral densities $J(\omega)$ of elements of $\hat{R}$ are usually smoothly varying functions that become small for $\omega\tau_c > 1$. If τ_c is small compared with the Larmor frequencies then all the J s can be replaced by their values at zero frequency, and the $\hat{R}\hat{\sigma}$ term can then be written as a pleasing double commutator of $\hat{K}$ with $\hat{\sigma}$. This operator expression is also applicable in a modified form for high-field NMR, where levels are grouped into collections having nearly the same energy.^{3,6,14} However, it is probably prudent to avoid using approximations in these operator methods for more complicated problems.

12 CONCLUSIONS

Weak relaxation theory was born with NMR, already well developed in BPP, and mature by the 25th anniversary of NMR. It achieved a new lease on life with the advent of FT NMR and, later, multidimensional methods, providing access to relaxation phenomena that were not dreamed of when the subject was developed. It is now virtually certain that computers will have a strong impact on the field, being able to predict the behavior of complex spin systems, to analyze data, and eventually to suggest better ways to obtain data, rather than relying on complicated analysis.

Experimentally, new developments will undoubtedly come from new pulse methods. An obvious general development will be the combination of pulse methods with high-speed high-resolution field cycling in some form, to map out completely the frequency dependence of spectral densities in a way that has so far been done only for the water resonance (described in *Dynamics of Water in Biological Systems: Inferences from Relaxometry*).

The theory we have described has had minor impact in other fields. Obviously, it is useful for electron paramagnetic

resonance. Theory equivalent to BPP has also been developed by Zusman and others to describe the nonadiabatic regime of electron transfer.¹⁸ Other forms of spectroscopy do not have the interesting variety of phenomena that NMR does, and such a theory is not needed.

1 INTRODUCTION

In the late 1960s and early 1970s, a number of experiments were developed that were aimed at performing ‘high-resolution NMR in solids’. In general, these techniques are classified into two general categories:

1. multiple pulse (MP) experiments, aimed at attenuating the homonuclear dipolar couplings in strongly coupled spin systems typically found in protonated solids;
2. dilute spin double resonance/cross-polarization (CP) experiments, which detect signals from magnetically dilute nuclei such as ^{13}C and ^{15}N in the presence of strong dipolar decoupling.

However, in both cases, the resulting spectra consisted of powder patterns due to shift anisotropies, or rather broad lines in spectra of single crystals. Thus, while the resolution of solid state spectra was much improved, it was still not comparable to that observed in liquids.

This situation changed dramatically with the marriage of magic angle spinning (MAS), a ‘partially successful’ mechanical rotation technique also developed to attenuate dipolar couplings in solids, with CP and/or MP to yield a new class of hybrid solid state techniques. In these cases, homo- or heteronuclear decoupling removes the dipolar interactions, and MAS narrows the shift anisotropy. The resulting spectra exhibit resolution comparable to that observed in liquids, and, as a consequence, these techniques are currently widely utilized in a variety of forms to examine problems in biology, chemistry, physics, materials science, and a number of engineering disciplines.

The subject of this article is the early developments that led to these MAS techniques, and advances in MAS that have occurred in the last 15 years or so. We focus primarily on the spectra of dilute $I = \frac{1}{2}$ spins in 1D and 2D experiments, with a brief interlude where we consider the possibility of reintroducing the dipolar coupling of the dilute spins to ^1H (so-called DIPSHIFT experiments), since this was the initial MAS ‘recoupling technique’. More recent advances in the area of homonuclear and heteronuclear recoupling (rotational resonance, DRAMA, RFDR, REDOR, TEDOR, etc.) are considered in other articles.

2 EARLY HISTORY

The initial MAS NMR experiments were performed in the late 1950s,^{1,2} and were aimed at attenuating homonuclear dipolar interactions in NMR spectra of solids, thereby revealing the underlying chemical shifts and scalar spin couplings. The approach was successful in cases where the dipolar couplings $|\hat{\mathcal{H}}_d|$ were not too large, and therefore the spinning rate $\omega_r/2\pi$ satisfied the condition $\omega_r/2\pi > |\hat{\mathcal{H}}_d|$. Early results obtained on ^{23}Na in NaCl, on ^{31}P in PCl_5 , and on ^{19}F in KAsF_6 demonstrated line narrowing, and resolution of chemical shifts and J couplings, respectively.^{3,4} However, in the 1960s, NMR spectrometers utilized iron magnets and continuous wave (CW) observation techniques, and this in turn constrained researchers to observe primarily ^1H and ^{19}F , which generally yield spectra with dipolar breadths of 25–50 kHz. Since available spinning speeds were in the range of 5–10 kHz, the spectra could not in general be narrowed, a result connected with the fact that $\hat{\mathcal{H}}_d$ is a *homogeneous* interaction.⁵ For this reason, for most of the 1960s and early 1970s, MAS was viewed as an interesting but not very useful technique.

During this period, several developments occurred that eventually led to a renaissance in MAS. First, in 1968, J. S. Waugh and co-workers introduced MP techniques for attenuating homonuclear dipolar couplings in solids.⁶ Since the cycle of four pulses in a WAHUHA experiment could be applied rapidly compared with the size of $|\hat{\mathcal{H}}_d|$, this technique, and its subsequent refinements,^{7–9} have been more successful than MAS in removing homonuclear dipolar couplings. In 1972, a second, very versatile approach to high resolution in solids emerged from Waugh’s laboratory. At that time, FT spectroscopy^{10,11} was developing as the preferred method of recording solution spectra, and reports describing spectra of less abundant nuclei (^{13}C , ^{15}N , etc.) were beginning to appear. It seemed reasonable that ^{13}C and ^{15}N spectra should also be observed in solids, and an approach for accomplishing this involving a Hartmann–Hahn¹² cross polarization and decoupling^{13,14} was described by Pines et al.¹⁵ While both MP and CP were very interesting developments, they both yielded spectra consisting of powder patterns or required single crystals; therefore, much of the high-resolution NMR community was unimpressed with the promise of the solid state NMR.

It was appreciated by at least a few individuals that an approach to narrowing these powder spectra was to incorporate MAS into the experiment.¹⁶ Specifically, any second-rank tensor—dipolar, chemical shift, quadrupole, Knight shift, and indirect dipolar couplings—is narrowed by MAS. Ultimately, this led to the Schaefer and Stejskal¹⁷ experiment, which demonstrated that high-resolution, ‘liquid-like’ spectra of solids could be obtained by combining dilute spin double resonance—cross polarization and decoupling—and MAS into what is now referred to as a CP MAS experiment. Later, Gerstein and co-workers¹⁸ performed similar experiments with MP and MAS, a technique now referred to as CRAMPS (combined rotation at the magic angle and multiple pulse).

Initially, CP MAS experiments were performed at a ^{13}C frequency of about 22.6 MHz, and therefore a typical 150–200 ppm ^{13}C shift tensor was 3.75–5.00 kHz wide, and near the regime $\omega_r/2\pi > \Delta\sigma$. Conventional wisdom dictated that line narrowing by MAS would not occur unless this condition was satisfied; therefore, spinning experiments should

Figure 1 Static (a) and MAS (b, c) ^{13}C spectra of zinc acetate, showing the effect of MAS on chemical shift anisotropic powder patterns. The spectra were obtained with a standard CP sequence. The rotational sidebands observed in (b) and (c) are spaced at the spinning frequency. The breadths of the powder patterns are 10.2 and 3.2 kHz, respectively, for the $-\text{CO}_2^-$ and $-\text{CH}_3$ resonances. Note that the sidebands for the methyl pattern are completely attenuated at $\omega_r/2\pi = 4.2$ kHz

be performed at low fields, and not in the superconducting solenoids that were becoming the standard polarizing field for NMR spectrometers. However, the results of performing MAS in the slow spinning regime, $\omega_r/2\pi < \Delta$, where Δ is the size of the interaction of interest, were already in the literature. In 1974, Andrew et al.¹⁹ showed that the Knight shift observed in Cd metal narrows into a sharp centerband and sidebands when the spinning rate is less than the breadth of the pattern. Subsequently, several other groups^{20–23} observed the same behavior for shift anisotropy powder patterns of ^1H decoupled spectra of $I = \frac{1}{2}$ nuclei: ^{13}C , ^{31}P , etc. Some examples of the type of spectra observed are shown in Figure 1, where ^1H -decoupled ^{13}C spectra of zinc acetate, H_2O (ZnAc) are illustrated as a function of spinning speed.

The CO_2^- and $-\text{CH}_3$ powder lineshapes are about 10.2 and 3.2 kHz wide, respectively, and evolve to a sharp centerband and sets of sidebands at spinning speeds of 4.2 kHz. These types of spectra are now routinely observed in the spectra of $I = \frac{1}{2}$ nuclei, and have brought solid state NMR into the realm of high resolution. Specifically, resolved centerbands and sidebands are observed for each magnetically inequivalent nucleus, and therefore MAS spectra can be used in much the same fashion as their high-resolution counterparts observed in solution. The remainder of this article will consider the shape of these spectra (i.e., the sideband intensities), new ways

of utilizing and manipulating sidebands, and multidimensional experiments.

3 HAMILTONIANS, ROTATIONAL ECHOES, AND SPECTRA

3.1 MAS Hamiltonian

The generalized laboratory frame Hamiltonian for a nuclear spin interaction is

$$\hat{\mathcal{H}} = C\hbar \sum_{l=0,2} \sum_{m=-l}^l (-1)^m \hat{R}_{l-m} \hat{T}_{lm} \quad (1)$$

where C is a collection of constants, and $\hat{R}$ and $\hat{T}$ are second-rank tensor operators containing the spatial and spin dependences of the coupling, respectively.²⁴ In a principal axis system (PAS), the tensor $\mathbf{R}$ representing $\hat{R}$ is diagonal, with principal values R_{ii} ($i = x, y, z$). These lead to an isotropic component

$$R = \frac{1}{3}(R_{xx} + R_{yy} + R_{zz}) \quad (2)$$

an anisotropy

$$\delta = R_{zz} - R \quad (3)$$

and an asymmetry

$$\eta = \frac{R_{xx} - R_{yy}}{\delta} \quad (4)$$

with the diagonal elements ordered so that

$$|R_{zz} - R| \geq |R_{xx} - R| \geq |R_{yy} - R| \quad (5)$$

The mechanical system under consideration consists of a rotor inclined at an angle θ relative to the external field $\mathbf{B}_0$ and spinning at ω_r . The laboratory frame with $z \parallel \mathbf{B}_0$ is related to the PAS of a specific coupling tensor $\mathbf{R}$ by two sets of Euler angles. The first transformation takes the laboratory into the rotor frame with Euler angles $(\theta_m, -\omega_r t)$, and the second maps the rotor frame onto the PAS of the coupling tensor. Using the definitions above and some algebra, we obtain a compact form for the MAS Hamiltonian. Specifically, for the chemical shift $\hat{T}_{00} = \hat{I}_z B_0$ and $\hat{T}_{20} = \sqrt{\frac{2}{3}} \hat{I}_z B_0$, we obtain

$$\begin{aligned} \hat{\mathcal{H}}(t) &= \omega(t) \hat{I}_z \\ &= -\Delta\omega \hat{I}_z - \omega_1 [g_1 \cos(\omega_r t + \varphi_1) + g_2 \cos(2\omega_r t + \varphi_2)] \hat{I}_z \end{aligned} \quad (6)$$

in which

$$\Delta\omega = \omega_1^0 + \omega_{\text{off}} = \frac{1}{3}\omega_0(\sigma_{11} + \sigma_{22} + \sigma_{33}) + \omega_{\text{off}} \quad (7)$$

$$\omega_1 = \omega_0(\sigma_{33} - \frac{1}{3}\text{Tr}\sigma) = \omega_0\sigma_{33} - \omega_1^0 \quad (8)$$

g_1 and g_2 depend on the Euler angles β and γ ,

$$g_1 = \frac{1}{2}(\frac{1}{2} \sin 2\theta \sin \beta) \times [(\eta \cos 2\gamma + 3)^2 \cos^2 \beta + \eta^2 \sin^2 2\gamma]^{1/2} \quad (9a)$$

$$g_2 = \frac{1}{2}(\frac{1}{2} \sin^2 \theta_m) \{[\frac{3}{2} \sin^2 \beta - \frac{1}{2} \eta \cos 2\gamma (1 + \cos^2 \beta)]^2 + \eta^2 \cos^2 \beta \sin^2 2\gamma\}^{1/2} \quad (9b)$$

The phase factors ϕ_1 and ϕ_2 are given by

$$\varphi_1 = \alpha + \phi_1 \quad (10a)$$

$$\varphi_2 = 2\alpha + \phi_2 \quad (10b)$$

where

$$\tan \varphi_1 = \eta \frac{\sin 2\gamma}{\eta \cos 2\gamma + 3} \cos \beta \quad (11a)$$

$$\tan \varphi_1 = \eta \frac{\cos \beta \sin 2\gamma}{\frac{3}{2} \sin^2 \beta - \frac{1}{2} \eta \cos 2\gamma (1 + \cos^2 \beta)} \quad (11b)$$

for axially symmetric tensors $\eta = 0$ and

$$\varphi_1 = \alpha, \quad \varphi_2 = 2\alpha, \quad (12)$$

Similar expressions can be derived for the heteronuclear dipolar Hamiltonian with $\hat{T}_{00} = 0$ and $\hat{T}_{20} \approx \hat{I}_z \hat{S}_z$ [in equation (1)]. Note that a term proportional to $3 \cos^2 \theta_m - 1$ must be added to equation (6) when the spinning is off the magic angle. Recently, a new approach for expressing the anisotropy of NMR Hamiltonians has been suggested involving the span $\Omega = \sigma_{33} - \sigma_{11}$ and skew $k = (\sigma_{11} + \sigma_{33} - 2\sigma_{22})/(\sigma_{33} - \sigma_{11})$ of the interaction. These definitions are discussed in *Sideband Analysis in Magic Angle Spinning NMR of Solids*.

3.2 Rotational Echoes

The spectra in Figure 1 result from the fact that the chemical shift interaction is *inhomogeneous*, a term used by Portis²⁵ to denote that a ‘hole could be burned’ into spectral patterns. In the absence of motion, continuous irradiation of one part of a powder pattern with a narrow frequency signal will saturate that part of the spectrum, and, because of the absence of coupling among the spins, that saturation will not diffuse through the spectral lineshape. In contrast, if the line is homogeneously broadened, for instance, if a homonuclear dipolar coupling determines the lineshape, then irradiation at a narrow band of frequencies will diffuse through the spin reservoir and lead to saturation of the entire spectrum. Thus, solid state spectra can be decoupled with single frequency irradiation, whereas liquids require wideband (noise or composite pulse^{26,27}) decoupling.⁵ Another approach to this statement is to consider the average Hamiltonian $\langle \tilde{\mathcal{H}} \rangle$ for an MAS experiment.^{22,24}

$$\langle \tilde{\mathcal{H}} \rangle = \sum_{\mu=0}^{\infty} \tilde{\mathcal{H}}^{(\mu)} \quad (13)$$

where the first two terms are

$$\tilde{\mathcal{H}}^{(0)} = \frac{\omega_r}{2\pi} \int_0^{2\pi/\omega_r} \hat{\mathcal{H}}(t') dt' \quad (14a)$$

$$\tilde{\mathcal{H}}^{(1)} = \frac{i\omega_r}{4\pi} \int_0^{2\pi/\omega_r} \int_0^{t''} [\hat{\mathcal{H}}_0(t'), \hat{\mathcal{H}}(t'')] dt' dt'' \quad (14b)$$

Because of the oscillatory nature of the MAS chemical shift Hamiltonian [see equation (6)], the time-dependent terms vanish, and the zeroth-order term $\tilde{\mathcal{H}}^{(0)}$ is equal to the isotropic shift. Physically, this tells us that the system returns to its initial state after each revolution of the spinner. In general, the higher order correction terms like equation (14b) will be nonzero, and when $|\tilde{\mathcal{H}}| \tau_c \gg 1$ (where τ_c is the cycle time), these terms interfere with the line narrowing. In the case of the ‘homogeneous’ homonuclear dipolar coupling, $\tilde{\mathcal{H}}^{(1)}$ is of substantial size, because the coupling between i and j does not commute with that between i and k , or j and k , etc. However, for the chemical shift, the commutator in equation (14b) vanishes, as do those in higher-order correction terms. For this reason, the chemical shift powder patterns are resolved into sideband patterns even in the slow spinning regime $\omega_r/2\pi < \delta$.

Finally, it should be mentioned that the heteronuclear dipolar and first-order quadrupolar couplings are also inhomogeneous, as is an isolated dipolar-coupled pair of like spins, and all of these cases will yield sideband spectra similar to those in Figure 1.⁵ However, when a homonuclear dipolar coupling is present, in addition to two or more spins with noncoaxial chemical shift tensors, the result is a homogeneous interaction that will not narrow completely. Some interesting examples of this last case are discussed below.

The average Hamiltonian describes the state of the system modulo the rotor period, but it says nothing about the evolution during the rotor cycle. In fact, what occurs for slow spinning is that the signal is recovered after each rotation as an echo, and for systems with reasonable decay times, a train of echoes is observed. The vanishing of $\tilde{\mathcal{H}}^{(0)}$ means that each echo will have the same shape, an example being shown in Figure 2(a). The Fourier transform of this train yields a centerband/sideband spectrum similar to those illustrated in Figure 1. The linewidths of the centerband and sidebands are determined by the decay time of the entire echo train, while the shape of the sideband envelope is governed by the shape of the rotational echoes.⁵

Our intuitive understanding of the behavior of single spins in liquids is enhanced by the use of vector pictures, which are very useful for depicting FIDs, Hahn spin echoes, and a number of other phenomena. Similarly, vector pictures provide insight into formation of rotational echoes and other phenomena associated with MAS. In Figure 3, we illustrate spin packet trajectories for two crystallites under MAS for a rotor period, and we have shrunk the length of the vector during the rotor period to clearly show its path. The magnetization trajectories are shown for three cases: before a π pulse is applied [(a) and (b)], after a single π pulse [(c) and (d)], and after two π pulses [(e) and (f)]. In all cases, the motion is τ_r -periodic, so that vectors return to their initial positions after a rotor period. We shall return to a discussion of this figure when we consider echoes. It has been shown²⁸ that a powder average of these spin packets leads to formation of

Figure 2 Rotational echo trains measured on a sample of $[1\text{-}^{13}\text{C}]$ -glycine spinning at $\omega_r/2\pi = 1.03$ kHz. The rf carrier frequency coincided with the isotropic chemical shift: (a) a train of unperturbed rotational echoes; (b) a single π pulse inserted at $\frac{3}{2}\tau_r$ results in the disappearance of the echo train; (c) two π pulses inserted at $\frac{3}{2}\tau_r$ and $\frac{5}{2}\tau_r$ result in the disappearance and reappearance of the echo train at $3\tau_r$; (d) multiple applications of $(-\pi_x - \tau_r - \pi_y - \text{echo})$ lead to the train with alternate echoes inverted; (e) echo train with $\tau_c = \frac{3}{5}\tau_r$ and alternating phases (0° and 90°) of the pulses; an inverted echo is recovered after $2n\tau_r = 6$ echoes and the intervening application of $2m\tau_r = 10$ π pulses; (f) echo train with $\tau_c = 2\tau_r$

the ‘rosette pattern’ illustrated in Figure 4. Here we show the path of the magnetization in a MAS experiment for a sample with $\delta = 5.4$ kHz, $\eta = 0$, and $\omega_r/2\pi = 2.0$ kHz, with a resonance offset of 200 Hz, and nine rotational echoes are apparent.

3.3 Spectra

There have now been many interesting applications utilizing these MAS spectra in biology, chemistry, physics, and materials science. These include studies of chemical exchange and other dynamic phenomena in solids, as well as studies of structure. In order to illustrate the explosive growth of MAS NMR in structural investigations, we present an illustration of the size of molecular system, which is often

Figure 3 Spin packet trajectories in the rotating frame, showing the effect of π pulses on rotational echo formation. All calculations used $\omega_r/2\pi = 2.0$ kHz, $\delta = 5.0$ kHz, $\eta = 0$, and $\beta = 60^\circ$. The position of the magnetization vector at $\frac{1}{2}\tau_r$ is represented by a dot, while the position of the vector at the end of the next rotor period is represented by a long arrow. The direction of motion of the vectors is indicated by arrowheads. The length of the vector was shrunk over time in order to make the paths clearer. (a) $\alpha = 60^\circ$: evolution from 0 to τ_r . (b) $\alpha = 20^\circ$: evolution from 0 to τ_r . (c) $\alpha = 60^\circ$: evolution from $\frac{1}{2}\tau_r$ to $\frac{3}{2}\tau_r$ after the first π pulse of phase 0° was applied at $\frac{1}{2}\tau_r$; a second π pulse of phase 90° was applied at $\frac{3}{2}\tau_r$. (d) $\alpha = 20^\circ$: same as in (c). (e) $\alpha = 60^\circ$: evolution from $2\tau_r$ to $3\tau_r$ after the application of the second π pulse of phase 90° at $\frac{3}{2}\tau_r$. (f) $\alpha = 20^\circ$: same as in (e)

Figure 4 (a) MAS spectrum for $\delta = 5.4$ kHz, $\eta = 0$ and spinning at $\omega_r/2\pi = 2.0$ kHz, 200 Hz off resonance. (b, c) The magnetization path corresponding to the MAS spectrum shown in (a) and its (x, y) projection. The petals in the rosette pattern correspond to the formation of rotational echoes

a limiting parameter in many magnetic resonance studies, that can be approached with this technique. Figure 5 shows spectra of a double ^{13}C -labeled membrane protein, $[14\text{-}^{13}\text{C}]\text{retinal-}[\varepsilon\text{-}^{13}\text{C}]\text{Lys-bacteriorhodopsin (bR)}$, which has not been crystallized and which cannot be effectively studied with solution NMR techniques because of its size and aggregation. The top trace in the figure contains lines due to both the label and the natural abundance background, while the middle

Figure 5 ^{13}C MAS spectra of dark-adapted bR collected at -80°C with a sample spinning speed of 2.8 kHz: (a) $[14-^{13}\text{C}]$ retinal- $[\epsilon-^{13}\text{C}]$ Lys-bR; (b) unlabeled bR; (c) the difference spectrum obtained upon subtraction of (b) from (a). The signals at 40, 48 and 53 ppm are due to the $[\epsilon-^{13}\text{C}]$ Lys label, and the signals in the 100–130 ppm range arise from the $[14-^{13}\text{C}]$ retinal marker resonances. Rotational sidebands are observed 35 ppm upfield and downfield of the centerbands

trace shows only the natural abundance spectrum. The bottom trace illustrates the difference spectrum exhibiting only the ^{13}C labels. Dark-adapted bR contains a 60 : 40 mixture of 13-*cis*- and all-*trans*-retinal (referred to as bR₅₅₅ and bR₅₆₈, respectively, where the numbers indicate the wavelengths of their absorption maxima). Therefore, there are two retinal and two Lys lines in the spectrum, together with a line due to six lysines not involved in the Schiff base linkage. bR has a molecular weight of 26.6 kDa, and the membrane is about 75 wt% protein, leading to an effective MW $\approx$ 35.5 kDa. Together, the two retinal and Lys Schiff baselines represent a single ^{13}C , and thus for the bR₅₆₈ resonances, we are observing about 40% of a single ^{13}C , corresponding to a single ^{13}C in a protein of MW $\approx$ 88 kDa. Further, it is possible with recoupling techniques (rotational resonance and RFDR) to measure the distance between the retinal and lysine labels, and to determine the conformation about the retinal C=N bond in both bR₅₅₅ and bR₅₆₈. Because of its ability to address protein problems of this size, MAS NMR will undoubtedly continue to find applications in many different areas.

4 MULTIPLE PULSE NMR IN ROTATING SOLIDS

In this section, we describe the effects of MP trains on MAS spectra. We first consider the effects of single and multiple π pulse trains on rotational echoes, since these effects are important in designing other experiments. This is followed by a discussion of the TOSS and scaling experiments, which are used to manipulate sidebands in MAS spectra. Several features of these experiments, including intensity losses and rotor frequency lines, will emerge from the discussion. Finally, we describe the hybrid, TOSS/scaling experiment, which combines desirable features of each approach.

4.1 π Pulses and Rotational Echoes

The simplest multiple pulse (≥ 2 pulses) experiment possible is the addition of π pulse(s) following excitation (cross polarization or a 90° pulse) analogous to a Carr–Purcell experiment in liquids. Experimental results showing the effects of π pulses during a rotor period are shown in Figure 2(b)–(f).

In Figure 2(b), a π_x pulse is applied at the middle of a rotor period, in this case $\frac{3}{2}\tau_r$, and the signal vanishes. This effect is readily understood by examining the single crystallite magnetization trajectories shown in Figure 3, where we have plotted the path for before [(a) and (b)] and after [(c) and (d)] the π_x pulse for two crystallite orientations: $\alpha = 60^\circ$, $\beta = 60^\circ$ (a) and $\alpha = 20^\circ$, $\beta = 60^\circ$ (b). Following excitation, both vectors lie along the x axis, evolve on the trajectories shown, and return to the origin after each rotor period, resulting in the formation of an echo. The application of a π_x pulse in the middle of a rotor period (corresponding to the position of the dot on the trajectory) results in a reflection of the trajectory about the x axis of the rotating frame. Thus, while the pulse does not affect the periodicity of the crystallite’s magnetization path, it does reorient each vector in a way that alters their phase relationship, and the signal disappears. A second π_x pulse at $\frac{5}{2}\tau_r$, again when the vector position is at the ‘dot’, restores the phase relation among the crystallites, and the echo train reappears [Figure 2(c)].

Another parameter of importance in echo phenomena is the relative phase of the rf pulses. In Figure 2(d), we show that the echo train may be inverted—in this case, multiple times from positive to negative to positive, etc.—by employing a 90° phase shift in the second of the two rf pulses. Specifically, instead of using $-\pi_x\tau_r\pi_x-$ for the refocusing, we use $-\pi_x\tau_r\pi_y-$. Thus, the initial ‘scrambling’ of the phases accomplished by the π_x pulse is reversed by a π_y pulse, but the refocusing occurs along the $\bar{x}$ rather than the x direction. This is easily understood by comparing Figures 3(c) and (d) with Figures 3(e) and (f), where the application of the π_y pulse results in refocusing along $\bar{x}$. Each new application of the $-\pi_x\tau_r\pi_y-$ sequence again reverses the sign of the subsequent echo, as shown in Figure 2(d).

As is discussed elsewhere,²⁹ there are many other combinations of π pulses that will yield echo trains, and the general conditions for echo formation in these trains have been studied. Specifically, for

$$\tau_c = \frac{n}{m}\tau_r \quad (15)$$

where τ_c is the cycle time, τ_r the rotor period, and n and m are integers, refocusing will occur only for odd m ; after $2m$ π pulses, echo formation will occur at $2n\tau_r$. Some results using this formula are shown in Figure 2(e) for $\tau_c = \frac{3}{5}\tau_r$ (a string of ten π pulses yields an echo at $6\tau_r$) and Figure 2(f), where $\tau_c = 2\tau_r$.

4.2 TOSS and Chemical Shift Scaling

The sidebands in a MAS spectrum, which reflect the anisotropic chemical shift, contain information that can be invaluable in understanding molecular and electronic structure.^{30,31} Nevertheless, in analytical applications of MAS,

the isotropic shift is the focus of attention, a fact that has provided the impetus to develop techniques to eliminate or attenuate sidebands. To date, there have been two approaches to the problem: the TOSS experiment, due originally to Dixon,³² and its subsequent variations,^{33–35} and scaling, due to Aue et al.^{36,37} The methods are based on fundamentally different physical principles, and each has its advantages and disadvantages.

The original four π pulse version of the TOSS pulse sequence is illustrated in Figure 6, and some experimental spectra obtained from $[1-^{13}\text{C}]$ glycine are shown in Figure 7. The top two spectra were taken at $\omega_r/2\pi = 3.20$ kHz with MAS (a) and TOSS (b), and the TOSS experiment clearly suppresses the rotational sidebands. The physical basis for TOSS is spin packet alignment—the preparation pulses result in a situation where the centerbands have the same amplitude and phase, and therefore add constructively. In contrast, the sidebands have different phases, add destructively, and are canceled when a powder average is performed. There is, however, a problem with this process, which is evident in Figure 7. First, the spectral intensity that resides in the sidebands is not transferred to the centerband by the alignment process. More specifically, when TOSS was first proposed, it appeared that the behavior illustrated in the top half of Figure 7 would always prevail. However, it was soon noticed that substantial intensity losses occur when the tensor is large or when the spinning speed low—i.e., when $\delta/(\omega_r/2\pi) \gg 1$.³⁸ The spectra in the bottom half of Figure 7 dramatically illustrate this point, in that the centerband inverts when $\delta/(\omega_r/2\pi) \approx 8$. Calculations and experimental data show that for an $\eta = 0$ tensor, the centerband intensity is positive when $\delta/(\omega_r/2\pi) \leq 6$; however, for larger values of this parameter, the intensity approaches zero, and becomes negative for $\delta/(\omega_r/2\pi) > 8$. Thus, TOSS centerband intensities cannot be employed to ‘count spins’ in the same fashion as normal NMR spectra, and the signal-to-noise ratio of the experiment is decreased substantially. In addition, since the pulse sequence is spread over 1–4 rotor periods, TOSS is difficult to apply to samples with broad NMR lines. Finally, with weak rf fields, the pulses sometimes overlap.

Despite these limitations, the idea suggested by Dixon is an important addition to the repertoire of MAS experiments, and its features have been explored extensively. Equations for the timing of the pulses have been presented,^{28,35,39} and have been solved analytically by Lang⁴⁰ and more recently by Levitt and co-workers.^{34,41} New timings⁴² and sequences have been explored, including the SELTICS sequence with continuous rf burst,³³ which suspends the chemical shift evolution. In addition, TOSS has been employed to examine

Figure 6 TOSS pulse sequence used to suppress rotational sidebands. The locations of the pulses and the initiation of sampling over two rotor periods are (in fractions of a rotor period) $b = 0.1763$, $c = 0.6289$, $d = 0.8617$, $e = 1.2060$, $f = 1.6485$, $g = 1.8170$, and $g = 1.9326$

Figure 7 Experimental MAS and TOSS spectra of $[1-^{13}\text{C}]$ glycine: (a) MAS at $\omega_r/2\pi = 3.2$ kHz; (b) TOSS at $\omega_r/2\pi = 3.2$ kHz; (c) MAS at $\omega_r/2\pi = 1.2$ kHz; (d) TOSS at $\omega_r/2\pi = 1.2$ kHz. The same phase correction was employed for all spectra. Note that the sideband intensity was not transferred to the centerband in (b) and that the centerband inverts when $\Delta\sigma/(\omega_r/2\pi) > 4.5$, as shown in (d)

chemical exchange,^{43–45} and can be usefully incorporated into 2D experiments to separate isotropic and anisotropic chemical shifts.²⁹

The second approach to attenuating sidebands involves incorporation of a MP experiment into a MAS experiment to reduce the effect size of the shift anisotropy. If the scale factor q is sufficiently small then $q \Delta\sigma/\nu_r < 1$, and the spectrum will be dominated by centerbands. This is based on the well-known fact that all multiple pulse trains scale certain interactions to varying degrees. For example, WAHUA and MREV-8, etc.^{6,7} scale $\hat{\mathcal{H}}_d^{I-I}$ to zero and the chemical shift by 0.57 and 0.47, respectively. The first experiment explicitly designed to scale chemical shifts was that of Ellett and Waugh.⁴⁶ More recently, Aue et al.^{47,48} developed improved scaling sequences, and used them to scale $^{13}\text{C}-^1\text{H}$ J couplings.

By itself, scaling will not reduce the sidebands in a MAS spectrum to zero, and therefore it is advantageous to combine scaling with TOSS in a hybrid experiment. The timings for the TOSS sequence must be adjusted to account for the scaling sequence,⁴⁹ but the result is a substantial increase in the signal strength of lines associated with large anisotropies. This is illustrated in Figure 8, where we show the MAS, TOSS, and TOSS/scaling spectra of alanine. A comparison of Figures 8(a) and (b) shows that, while TOSS does suppress sidebands, it does little to enhance the $-\text{CO}_2^-$ centerband intensity. However, as shown in Figure 8(c), the presence of a scaling sequence distills the intensity of the $-\text{CO}_2^-$ sidebands into the centerband so that the three lines are of approximately equal intensity, as expected. In the process, the intensity of

Figure 8 79.9 MHz ^{13}C spectra of natural abundance Ala obtained at $\omega_r/2\pi = 1.5$ kHz. (a) MAS spectrum showing the numerous sidebands arising from the $-\text{CO}_2^-$ group and the narrow centerbands from the $-\text{CH}_3$ and $\alpha\text{-CH}$ carbons. (b) TOSS spectrum illustrating the attenuation of the sidebands and the loss of intensity that occurs for the $-\text{CO}_2^-$ centerband—i.e., it should be of equal intensity to the other lines in the spectrum. (c) TOSS/Scaling spectrum demonstrating that the signal intensity present in the rotational sidebands may be transferred to the centerband. The noise in the baseline has increased owing to the greater bandwidth used for the integrate-and-hold circuit that sampled the magnetization

the $-\text{CO}_2^-$ centerband increases by a factor of approximately five.

4.3 Rotor Frequency Lines and Powder Lineshapes

In a multiple pulse experiment, a factor responsible for limiting resolution is the (lack of) perfection of the pulse train. In fact, the development of pulse sequences that compensate for pulse errors has been a major industry in NMR. The effects of pulse errors also appear in MAS multiple pulse

experiments—but in an unexpected manner. In many practical cases, a scaling or CRAMPS experiment with a scale factor of 0.5 will move the intensity to the centerbands, which are then readily identifiable. In addition, however, extra lines appear in the spectra at $0, \pm n\omega_r/2\pi$, etc., which are referred to as *rotor frequency lines*.^{28,36,37} These lines are also observed in ^1H CRAMPS spectra and appear and disappear as the resonance offset is changed.^{36,37,50}

A theoretical explanation of these phenomena^{28,50} is rather lengthy and involved. Physically, the origin of rotor lines is the presence of small pulse errors, which create components perpendicular to the average Hamiltonian and lead to a significant alteration in the paths of the magnetization vectors. For example, if a small (about 2%) pulse error is included in the calculation—the scaling is performed with $270^\circ_x, 265^\circ_{\bar{x}}$ pulses rather than $270^\circ_{x(\bar{x})}$ pulses—then rotor frequency lines at 0 and $\pm n\omega_r/2\pi$ appear in the spectra. Concurrently, the intensity is reduced, since the signal goes into the rotor line rather than the real spectrum.

Finally, it should be mentioned that scaling, MREV-8, and other multiple pulse experiments function well as long as the cycle times of the experiments satisfy the condition $\tau_c < \tau_r$. In practice, this means there are three or more pulse cycles per rotor period. With fewer cycles, $\tau_c \approx \tau_r$ and a number of interesting phenomena occur. For example, when $2\tau_c = \tau_r$, powder patterns rather than sharp lines appear in the spectra, albeit in distorted forms.^{20,36,37,51,52}

5 MULTIDIMENSIONAL MAS EXPERIMENTS

In this section, we review some of the early and simplest multidimensional MAS experiments employed for resolving and correlating various interactions in solid state NMR spectra. Our discussion will focus primarily on 2D experiments for

1. separation of isotropic and anisotropic chemical shifts;
2. separation of the heteronuclear dipolar interaction and chemical shifts;
3. heteronuclear chemical shift correlation spectroscopy;
4. 2D chemical exchange experiments.

This is currently a rapidly expanding area, and correlation experiments involving other homonuclear and heteronuclear dipolar interactions are discussed in *Homonuclear Recoupling Schemes in MAS NMR* and *REDOR and TEDOR*.

5.1 Isotropic and Anisotropic Chemical Shifts

As discussed above, MAS NMR spectra sometimes display large numbers of sidebands, which degrade the resolution. Restoration of the resolution provided the impetus for the development of the TOSS, Scaling, and TOSS/Scaling experiments. However, since these experiments discard two-thirds of the information available in the spectra, it is useful to consider methods to restore these data. This problem was originally addressed with a 2D experiment with isotropic chemical shifts on one axis and isotropic and anisotropic on the second.³⁷ In order to extract the isotropic spectrum, the magnetization was sampled synchronously with the rotation in the $\omega_1/2\pi$ dimension, yielding the isotropic spectrum, and sampled without restriction in $\omega_2/2\pi$, which will contain both isotropic and anisotropic shifts. The difficulty

with synchronous sampling is the limited bandwidth in the $\omega_1/2\pi$ dimension (typically ± 2 – 4 kHz), which is too small to accommodate the dispersion of isotropic ^{13}C shifts at superconducting fields (about 20 kHz). Therefore, the spectra will be aliased in this dimension, and, for example, lines from the $-\text{CH}_3$, $-\text{CH}_2-$ region of the spectrum will appear in the aromatic/carboxyl region. However, the $\omega_2/2\pi$ dimension contains *redundant* information—namely, both the isotropic and anisotropic shifts—and, for this reason, this sort of problem will not generally occur. Nevertheless, in certain situations, the 2D spectrum will not be completely resolved—in particular, when two resonances, δ_i and δ_j , satisfy the following two conditions: (i) $\delta_i - \delta_j = n\omega_r/2\pi$ and (ii) their shift anisotropies are sufficiently large that their sideband patterns overlap. Because the isotropic shifts are separated by $n\omega_r/2\pi$, they occur at the same frequency in $\omega_1/2\pi$, and their sideband patterns are then overlapped. However, by incorporating chemical shift scaling into the t_1 dimension, it is possible to circumvent this problem and to affect a complete resolution of the spectrum.³⁷

A second solution to this problem is the TOSSOT experiment,²⁹ whose pulse sequence is shown in Figure 9, and will be recognized as forward and reverse TOSS. Initially, the TOSS sequence prepares magnetization to yield a t_1 period of isotropic evolution, while the time-reversed TOSS restores the anisotropic spectrum during t_2 . The physical basis for the experiment is that the spin packet alignment resulting from TOSS can be restored at any time subsequent to its preparation by a mirror image sequence. However, TOSS must be initiated at the peak of a rotor echo to perform sideband suppression. Thus, in the present scheme, it is not possible to initiate TOSS at an arbitrary time in a rotor period. In addition, the TOSSOT scheme does show significant resonance offset effects, so care must be exercised in extracting anisotropies. Nevertheless, the experiment functions well in performing a 2D separation of isotropic shifts in $\omega_1/2\pi$ and isotropic plus anisotropic in $\omega_2/2\pi$. A 2D resolved spectrum of Tyr · HCl taken at $\omega_r/2\pi = 1.7$ kHz illustrating the technique is shown in Figure 10. Note the substantial sideband manifolds present for the aromatic lines, which are clearly separated by their isotropic chemical shift. These lines are strongly overlapped in the 1D projection shown at the top.

The TOSSOT experiment has recently been employed by Geen and Bodenhausen^{43,44} in studies of chemical exchange and in observation of isotropic chemical shifts.

Figure 9 TOSSOT (TOSS/reverse TOSS) pulse sequence for 2D resolution of isotropic and anisotropic chemical shifts. The interpulse delays measured from the centers of the π pulses were (in fractions of a rotor period) $a = 0.1226$, $b = 0.0773$, $c = 0.2236$, $d = 1.0433$, and $e = 0.7744$

Figure 10 2D resolved ^{13}C TOSSOT spectrum of Tyr · HCl, $\omega_r/2\pi = 1.7$ kHz. The normal MAS spectrum is given at the top and the ω_1 projection on the left. Slices in ω_1 with negative intensity were phase-reversed in the ω_1 projection. The ^{13}C pulse length was 8.0 s

5.2 Heteronuclear Dipolar and Chemical Shift

The heteronuclear dipolar coupling, like the chemical shift, is an inhomogeneous interaction, and will therefore yield sharp sidebands in a MAS experiment. Thus, if homonuclear couplings can be suppressed with an MP train, it is possible to separate the heteronuclear dipolar interaction and the chemical shift in a 2D correlation experiment. The Hamiltonian for this system is conveniently written as

$$\hat{\mathcal{H}} = a(\Omega, t)\hat{S}_z + b(\Omega, t)\hat{I}_z\hat{S}_z + c(\Omega, t)\sum_{i,j}(\hat{I}_i \cdot \hat{I}_j - 3\hat{I}_{iz}\hat{I}_{jz}) \quad (16)$$

where we have collected the angular and temporal dependence in the coefficients $a(\Omega, t)$, $b(\Omega, t)$, and $c(\Omega, t)$. There are several pulse sequences that can be used to affect the desired separation, two of which are shown in Figure 11. The magnetization is prepared by cross polarization, and during t_1 , the $a(\Omega, t)$ and $c(\Omega, t)$ terms are removed from equation (16) by application of a refocusing pulse and MREV-8, respectively. What remains during t_1 is the heteronuclear $\hat{I}_z\hat{S}_z$. During t_2 , ^1H decoupling is applied, removing the $b(\Omega, t)$ and $c(\Omega, t)$ terms and leaving the chemical shift term $\hat{S}_z$. In addition, spectra are often recorded in the regime $\omega_r/2\pi < \Delta\sigma$, so we initiate sampling at the peak of a rotational echo to ensure the proper phase relationship among the sidebands in the chemical shift domain; t_1 thus runs from 0 to $N\tau_r$, and sampling commences at $2N\tau_r$.

The 2D dipolar/chemical shift (DIPSHIFT) spectra obtained from this experiment consist of a matrix of sidebands spaced at $\omega_r/2\pi$ in each dimension, which display two unusual features illustrated in Figure 12. The dipolar slices corresponding to chemical shift sidebands are asymmetric, and inverted sidebands are present in some of the slices. The origin of this effect has been discussed elsewhere,⁵³ and is due to the weighting of symmetric dipolar slices by the chemical shift,

Figure 11 Pulse sequences for 2D dipolar-chemical shift spectroscopy. (a) The constant time experiment with a rotor synchronized π pulse to refocus isotropic chemical shifts at $N\tau_r$. Acquisition commences at $2N\tau_r$. (b) Simplified experiment where a shearing transformation is required to align the sideband manifolds

leading to asymmetric and inverted sidebands. The dipolar slices corresponding to four sidebands and a centerband for the ^{15}N - ^1H DIPSHIFT spectrum obtained from *N*-acetyl-DL-valine is shown in Figure 12, and the asymmetric intensities in the dipolar slices and inverted sidebands are apparent. When a full powder average is performed—i.e., when the dipolar and chemical shift spectra are projected onto the $\omega_1/2\pi$ and $\omega_2/2\pi$ axes, respectively—these two features disappear, as shown in Figure 12. The experimental spectrum and simulation of Figure 12 agree extremely well, and yield $r_{\text{NH}} = 104.9 \pm 0.3$ pm and an angle between the σ_{33} element of the tensor and the NH direction of 22° in agreement with single crystal studies. Differences in tensor orientation as small as 5° lead to sideband intensities that are perceptively different.

The salient feature of the DIPSHIFT experiment is that it can locate protons in polycrystalline or amorphous solids. This cannot be done accurately with X-rays, and instead requires a neutron diffractometer and large single crystals. Furthermore, the NMR experiment is relatively easy to perform, and can yield proton-rare spin bond distances with a precision of better than 0.5% and relative orientations of tensors to less than 5° . This has been studied in an experimental comparison of neutron and NMR data,⁵⁴ and the NMR bond distances are consistently about 3.5 pm longer than the diffraction results owing to different vibrational averaging.⁵⁵ Otherwise, there is an excellent correlation between the two techniques, indicating that DIPSHIFT-type experiments can be used to obtain structural data on polycrystalline samples.

There have been a number of other versions and applications of DIPSHIFT experiments. For example, the sequence shown in Figure 11(b) yields the same spectra as Figure 11(a), but with improved signal-to-noise, since there is only a delay of t_1 prior to sampling. However, the slices in the chemical shift dimension must be corrected with a shearing transformation.⁵⁶

Figure 12 2D dipolar chemical shift spectra of ^{15}N -acetyl-DL-valine (NAV) $\omega_r/2\pi = 2.000$ kHz. Slices were taken on points corresponding to sideband frequencies in ω_2 . (a) Spectrum from the experiment of Figure 11 after shearing. (b) Simulation using the chemical shift tensor, the N-H bond length, and the nutal orientation of the chemical shift and dipolar tensors of NAV; $\sigma_{11} = -64.7$ ppm, $\sigma_{22} = -39.7$ ppm, $\sigma_{33} = 104.4$ ppm and $r_{\text{NH}} = 105$ pm. Polar angles of the NH bond in the principal axis system of the N shielding tensor are $(\theta, \phi) = (22^\circ, 0^\circ)$. The multiple pulse scaling factor was $\kappa = 0.480$

In addition, sequences with scaling and double windows^{57,58} have been described, as have measurements of bond distances in DNA⁵⁹ and studies of dynamics of aromatic rings in polymers.⁶⁰

5.3 Heteronuclear Correlation Spectra

Another 2D experiment that is extremely useful in solution NMR is heteronuclear correlation spectroscopy,⁶¹ where, for example, the ^{13}C spectrum is used to increase dispersion of the ^1H spectrum. Since resolution in the ^1H spectra of solids is relatively poor, it could possibly be improved with such a technique. The basic sequence for correlation spectroscopy has a preparation period consisting of a 90° pulse on ^1H , and during the evolution, a multiple pulse train is applied to ^1H while decoupling ^{13}C ; thus, only ^1H chemical shifts persist. This is followed by a mixing period and detection of ^{13}C in the presence of ^1H decoupling. During the mixing period, several schemes can be employed to transfer coherence between the spin reservoirs. Some possibilities considered by Roberts et al.⁶² were normal cross polarization, single pulse transfers, and pulse transfers involving MREV-8, while Caravatti et al.⁶³ proposed an interesting windowless isotropic mixing sequence (WIM) for this purpose. The optimal mixing technique depends somewhat on the sample being studied. For molecules like adamantane and *cis*-polybutadiene, the pulse transfer schemes work well, whereas for rigid solids the simultaneous MREV-8 cycles or the WIM sequence are preferable because of their selectivity. Burum and Bielecki⁶⁴ have further improved these schemes,

focusing on the homonuclear and heteronuclear decoupling during the evolution period.

5.4 Dynamic Processes in Solids

Over the last decade, several groups have employed MAS in 2D exchange experiments for solids.^{65–68} Typically, these experiments have involved studies of intramolecular proton transfer processes or the dynamics of motion of aromatic rings or polymers.⁴⁵ In the fast spinning limit ($\Delta\sigma/\nu_r < 1$), the solid state experiment is a simple modification of Jeener's classic three-pulse sequence,³⁹ except that the first $\frac{1}{2}\pi$ pulse in Jeener's sequence is typically replaced by cross polarization, and ^1H decoupling is applied during t_1 and t_2 . In the opposite high-field limit, where the 1D spectrum exhibits sidebands ($\Delta\sigma/\nu_r > 1$), the 2D spectrum will be complicated by 'self-cross peaks' between every sideband in a sideband family, even if that resonance is not undergoing exchange. Veeman and

co-workers⁶⁶ demonstrated that an exchange spectrum may be observed when $\Delta\sigma/\nu_r > 1$, provided that the mixing period is synchronized with the rotor period.

Clearly, isotropic evolution during t_1 (or t_2) will eliminate self-cross peaks, and the exchanging signals will not be dispersed over sidebands in either dimension. In early experiments, this was accomplished by working at low fields or by inserting chemical shift scaling into t_1 , which focused the intensity into the centerband. Thus, proton transfer in tropolone⁶⁵ and slow aromatic ring flips occurring with a time constant of about 4 s in *p*-nitroanisole were examined.⁶⁷ More recently, a variety of slow motions in polymers have been studied,⁴⁵ as well as intermolecular exchange processes involving proton transfers in oxalic acid dihydrate between the COOHs and H₂O of hydration.⁶⁹ 2D ^1H spectra (obtained from ^2H -labeled samples to eliminate ^1H dipole broadening) showing cross peaks due to this exchange process are shown in Figure 13. The exchange has a rate constant of about 55 s^{-1} at 17°C and $E_a \approx 35.6\text{ kJ mol}^{-1}$. The 2D experiment is also extremely useful in elucidating complicated exchange networks in solids, as shown by spectra of the complex of oxalic acid and ammonium hydrogen oxalate hydrate.⁶⁹

Figure 13 2D 400 MHz ^1H spectra of oxalic acid dihydrate (90% ^2H -labeled) obtained with the Jeener three-pulse (NOESY) sequences. Note the cross peaks due to proton transfer between the $-\text{COOH}$ and H_2O moieties

1 INTRODUCTION

The phenomenon of a Nucleus with a magnetic moment, placed in a Magnetic field, Resonating with a radiofrequency excitation (NMR), first reported^{1,2} in 1946, has become one of the single most powerful quantitative and qualitative analytical tools for the physical scientist, materials scientist, biological scientist, geologist, and medical diagnostician.³ In this section, we consider some simple ideas that may lead to an understanding of why such a strong statement is made. We shall just consider a classical picture of NMR for purposes of a simple introduction to the field. Both the classical and quantum pictures are provided in a more comprehensive treatment⁴ not appropriate to this Encyclopedia.

Consider a child's top, which is initially lying at rest on the floor. The child grabs the handle, and excitedly proceeds to pump it up and down to set the top spinning. Here, at least four different phenomena may be observed. First is the vigorous action of the child in setting the top in motion; in this case, a 'pumping' of the handle, which imparts a circular motion to the top via a vertical up-and-down motion of the handle. Second is just the spinning. Soon, as the spinning axis becomes tipped from the perpendicular, i.e., from alignment of the spinning axis with the Earth's gravitational field, a wobble, or precession, is also seen. This precession is the natural consequence of the reaction of an angular momentum, in this case that of the spinning top, with its vector aligned along the spinning axis, to a noncollinear field, here the Earth's gravitational field perpendicular to the surface of the Earth. Finally, if left alone after the energy has been pumped into the top to set it spinning, the top will relax to its initial equilibrium position lying on the floor. So, we have excitation, precession, and relaxation. Exactly the same phenomena may be observed among some nuclei placed in a magnetic field, and pumped with radiofrequency energy. One of the intriguing aspects about nuclear magnetic resonance, which is fundamentally a quantum mechanical phenomenon, is that there are such easily

understood classical analogs to many of the phenomena that may be observed in NMR. Let us look at some of these. In doing so, of course, we will invoke the fact that nuclei are really particles that must obey quantum mechanics, and therefore behave discretely.

2 CLASSICAL MECHANICS OF PRECESSION: MAGNETIC RESONANCE

The classical mechanics of the precessional motion of a spinning body in a field $\mathbf{g}$, say, is well understood: a spinning body with mass m at a distance $\mathbf{r}$ from the spinning axis possesses an angular momentum $\mathbf{L}$. There is a torque, i.e., a twisting force, upon the body. This torque, $\mathbf{G}$, say, is perpendicular with both the angular momentum $\mathbf{L}$ and the field $\mathbf{g}$, and so is proportional to their cross product: $\mathbf{G} = \Gamma \mathbf{L} \times \mathbf{g}$. Torque is the rate of change of angular momentum with time (similarly to the way in which force is the rate of change of momentum), and so we have the equation of motion

$$\mathbf{G} = \frac{d\mathbf{L}}{dt} = \Gamma \mathbf{L} \times \mathbf{g} \quad (1)$$

The resulting classical motion is obviously a precession of the angular momentum vector about the field, at angular velocity $\boldsymbol{\omega} = -\Gamma \mathbf{g}$ (i.e., with precession frequency $\omega = \Gamma g$), as illustrated for the top in Figure 1.

One picture that we have of the nucleus (e.g., of the proton, which is the nucleus of the hydrogen atom) is that of a spinning electric charge. The spinning imparts an angular momentum to the charge. The fact that it is a charge, e , that is spinning imparts a magnetic moment to this hydrogen nucleus, in the same manner in which we create a magnet by running a current through an inductor. The classical relation between a charge e of mass m circulating about an area A with linear velocity v , resulting in a current i and the magnetic field $\mathbf{B}$ created by this situation and aligned along the $\mathbf{k}$ direction (the z axis) in space corresponds to the existence of a magnetic moment

Figure 1 Motion of an angular momentum $\mathbf{L}$ in a field, as illustrated by the motion of a child's toy top in the Earth's field $\mathbf{g}$

$$\begin{aligned}\frac{M}{4\pi} &= \frac{kiA}{c} = k \frac{dq}{dt} \frac{A}{c} = k \frac{m}{m} e \frac{v}{2\pi r} \frac{A}{c} = k \frac{emv}{2mc\pi r} \frac{\pi r^2}{c} \\ &= k \frac{mvre}{2mc} = e\mathbf{r} \times \frac{m\mathbf{v}}{2mc} = \frac{e\mathbf{r} \times \mathbf{p}}{2mc} = \frac{e\mathbf{L}}{2mc} \equiv \gamma \mathbf{L} \quad (2)\end{aligned}$$

We see, then, that we may expect the nucleus of a hydrogen atom to have a magnetic moment that is proportional to the nuclear angular momentum $\mathbf{L}$. Since nuclear momenta come quantized in units of $\hbar/2\pi$, we write the nuclear angular momentum in terms of the quantum number I , with the total nuclear angular momentum being $\mathbf{L} = 2\pi I$. So the magnetic moment is given by the magnetogyric ratio times the angular momentum: $\boldsymbol{\mu} = (e/2mc)\mathbf{L} \equiv \gamma \mathbf{L}$. The correct quantum mechanical result is a factor of two higher, namely, e/mc . The classical equation of motion of this moment in a magnetic field $\mathbf{B}$ is

$$\frac{d\boldsymbol{\mu}}{dt} = \gamma \boldsymbol{\mu} \times \mathbf{B} \quad (3)$$

and the classical motion is a precession of $\boldsymbol{\mu}$ about the field $\mathbf{B}$ with angular frequency $\omega = -\gamma B$. In quantum mechanics, of course, I becomes an operator $\hat{I}$ with magnitude $[I(I+1)]^{1/2}$, and the allowed projections of $\hat{I}$ along the z axis of quantization (as set by an external magnetic field) are given by the allowed quantized values of $\hat{I}_z$, the component of $\hat{I}$ along the field, which range from $-I$ to $+I$ in steps of unity. For a proton, $I = \frac{1}{2}$, and the allowed expectation values of $\hat{I}_z$ are $-\frac{1}{2}$ and $+\frac{1}{2}$ in units of $\hbar/2\pi$. With the classical energy of a magnetic moment $\boldsymbol{\mu}$ in a field $\mathbf{B}$ being

$$E = -\boldsymbol{\mu} \cdot \mathbf{B} = -\gamma \mathbf{L} \cdot \mathbf{B} \quad (4)$$

which corresponds to magnets aligning north–south, north–south beside each other, we see that a classical picture of a quantized moment $\hat{\boldsymbol{\mu}} = \gamma \hat{\mathbf{I}}$ in a magnetic field $\mathbf{B}$ corresponds to discrete energies

$$E_{1/2} = -\frac{1}{2}\gamma B_0 \equiv -\frac{1}{2}\omega_0 \quad (5a)$$

$$E_{-1/2} = \frac{1}{2}\gamma B_0 \equiv \frac{1}{2}\omega_0 \quad (5b)$$

in which the classical motion of the ‘high’ energy state, with energy $E_{-1/2}$, is a precession of the classical vector $\boldsymbol{\mu}$ about the field $\mathbf{B}$, with the component of $\boldsymbol{\mu}$ along the field being oriented in the same direction as the field, as shown in Figure 2. Similarly, the ‘low’ energy state, with energy $E_{1/2}$, corresponds to a classical motion in which $\boldsymbol{\mu}$ precesses about $\mathbf{B}$, but has direction aligned oppositely to that of $\mathbf{B}$, as would the energy of two bar magnets be minimized if they were aligned north–south, north–south, and maximized if they were aligned the other way.

In summary, we have the following.

1. Many nuclei have magnetic moments, with the relation between the classical moment and the quantized angular momentum being $\hat{\boldsymbol{\mu}} = \gamma \hat{\mathbf{I}}$.
2. In a magnetic field $\mathbf{B}$, the classical motion of these nuclei is a precession about $\mathbf{B}$.
3. Since the nuclear moments are quantized, only discrete precessional states are allowed, and these correspond to energies (in units of frequency) $-I\omega$, $-(I-1)\omega$, $\dots$, $I\omega$.

Figure 2 Energies of the two z components of the angular momentum of a spin-1/2 nucleus in a field $\mathbf{B}$

In the article *Nuclear Spin Properties and Notation* is given a table of the magnitudes of the magnetic moments of nuclei, and their precessional frequencies for a fixed field. For example, in a field of 2.3 T, the nuclide ^{13}C will precess at an angular frequency of $\omega = 2\pi \times 25 \times 10^6 \text{ rad s}^{-1}$, corresponding to a frequency $\nu = 25 \text{ MHz}$. Note the relation $2\pi\nu = \omega$.

An immediate translation of the above ideas is that when a nucleus (e.g., ^1H) with spin quantum number $I = \frac{1}{2}$, is in a magnetic field $\mathbf{B}_0$, its lowest energy state will be with its moment aligned against the field, and precessing happily at its Larmor frequency $\omega_0 = \gamma B_0$, corresponding to the vector picture $\boldsymbol{\omega}_0 = -\mathbf{B}_0$. The magnitude of the precessional frequency is familiar to those who listen to FM radio; it is in the radiofrequency range of tens to hundreds of megahertz. If, therefore, a frequency matching this precessional frequency is applied to this nucleus precessing in a field, a possibility is that the nucleus will ‘resonate’ with this precessional frequency, in much the same manner that a car wheel that is out of balance will cause a vibration of the car suspension system when the ‘natural’ vibrational frequency of the wheel’s rotation and that of the suspension system match each other. The nucleus can absorb energy from the radiofrequency field, but, since it is a sufficiently small particle, it must obey quantum mechanics, and its energies are quantized—for a proton, by $\Delta E = E_{1/2} - E_{-1/2} = \hbar\omega_0$. This resonance of a nucleus being driven by a radiofrequency oscillation in a magnetic field is called NMR, nuclear magnetic resonance. Of course, once a system absorbs energy, if allowed sufficient time, it will relax to its initial equilibrium state, as did the child’s top when it slowed, and finally rolled to a stop, which was its state before the child excited it by pumping the handle. In fact, both the absorption of energy to an excited state and the emission of energy accompanying relaxation to the equilibrium ground state involve relaxation processes—the first a ‘relaxation’ to the ‘new’ equilibrium state in the presence of a driving excitation, and the second to the old equilibrium state in the absence of the excitation. Let us look at this business of ‘relaxation’ in a bit more detail.

3 THE BLOCH EQUATIONS: RELAXATION IN THE CLASSICAL SYSTEM

Imagine an ensemble of nuclear spins $I = \frac{1}{2}$, for example, ^1H in $\text{H}_2\text{O}(\text{gas})$. Classical thermodynamics tells us that at equilibrium in the absence of fields (e.g., magnetic, gravitational, and electric fields) the number of macroscopic variables that completely specify the state of this system is $C + 2$, where C is the number of compounds or elements needed to prepare the system in the specified state. For example in the case of gaseous water, $C = 1$, since we need only take water from the tap to prepare the system as described. For $\text{H}_2\text{O}(\text{g})$, $C + 2 = 3$, and only three of the four total variables, which are the extensive variables n and V , and the intensive variables P and T , are needed to uniquely specify the state described by $PV = nRT$. Now let us place this water vapor, suitably contained in an NMR tube, in the magnetic field of, let us say, a magnet with static field 2.3 T, by putting the tube in the inductor of the tuned circuit (see *Probes for High Resolution*) of an NMR probe that is in this 2.3 T magnet. Suddenly, the situation changes drastically. The nuclear moments μ , which previously could align themselves in any direction in space (ignoring the Earth's small magnetic field—but see *Well Logging*), now find themselves in a highly anisotropic environment. In one direction (let us call it the z direction to conform with convention), there is a field vector $\mathbf{B}_0 = k\mathbf{B}_0$, while the other directions in the (x,y) plane have no field component at all. These moments suddenly find themselves in the situation that their quantized levels $E_{1/2}$ and $E_{-1/2}$ are being pried apart by the internal field vector $\mathbf{B} = \mu_0\mu\cdot\mathbf{H} \equiv \mu_0(\mathbf{1} + \chi)\cdot\mathbf{H}$. Here $\mu_0 = 4\pi \times 10^{-7} \text{ H m}^{-1}$, and χ is the rationalized volume susceptibility (see *Magnetic Susceptibility and High Resolution NMR of Liquids and Solids*). Suddenly, the number of variables describing the equilibrium state of this system changes from $C + 2$ to $C + 5$ as $\mathbf{H}$ is added. The number is $C + 5$ because $\mathbf{H}$ has three vector components H_x , H_y , and H_z , leading to the internal field seen by the protons in this system being $B_x = 0$, $B_y = 0$, and $B_z = B_0$. The moments must relax to this new equilibrium situation, and clearly do so in an anisotropic manner, since now the z direction in space differs drastically from the x and y directions, which are equivalent for purposes of describing the anisotropy of the environment in this case.

We have seen that in a magnetic field, the equation of motion of a microscopic moment μ_k , an ensemble of which leads to a macroscopic moment $\mathbf{M} = \sum_k \mu_k$, is given by equation (3). In the presence of relaxation processes, the equations of motion of the three components of the macroscopic magnetic moment are the cross product from equation (3) plus relaxation: $d\mathbf{M}/dt = \gamma\mathbf{M} \times \mathbf{B} + \text{relaxation}$. (The details of this relaxation involve rather more quantum mechanics than there is room for here—and, indeed, are beyond the scope of this article—but for a simple example, see Chapter 2, Section IV of Gerstein and Dybowski.⁴) The simplest form of equations describing the kinetics of relaxation were first developed by Bloch, who assumed simple first-order kinetics, with rate constants $1/T_1$ for the z direction, and $1/T_2$ for the (x,y) plane. So, including relaxation, the equations of a moment in a field become

$$\frac{dM_z}{dt} = -\frac{M_z - M_z^{\text{eq}}}{T_1} \quad (6a)$$

$$\frac{dM_x}{dt} = \gamma M_y B - \frac{M_x - M_x^{\text{eq}}}{T_2} \quad (6b)$$

$$\frac{dM_y}{dt} = -\gamma M_x B - \frac{M_y - M_y^{\text{eq}}}{T_2} \quad (6c)$$

where the superscript 'eq' indicates the equilibrium value. Equation (6a) is of the form $y = dx/x$, and can be solved immediately to yield

$$M_z(t) = M_z^{\text{eq}} + [M_z(0) - M_z^{\text{eq}}]e^{-t/T_1} \quad (7a)$$

The approach to equilibrium of the z component is a simple exponential. This immediately tells us that when we place our water vapor sample in the magnet, we must wait roughly $5T_1$ for the nuclei to polarize along the magnetic field to 99% of their full polarization. Since relaxation to the equilibrium value caused by the sudden introduction of a magnetic field involves alignment along the longitudinal z axis, such relaxation is sometimes termed 'longitudinal' relaxation. For reasons not obvious here, it is also termed 'spin-lattice' relaxation.

The x and y components form a coupled set of differential equations. These can be decoupled (for a general method for doing this, see page 77 of Gerstein and Dybowski⁴), to give

$$M_x(t) = e^{-t/T_2} [M_x(0) \cos \gamma B t + M_y(0) \sin \gamma B t] \quad (7b)$$

$$M_y(t) = e^{-t/T_2} [-M_x(0) \sin \gamma B t + M_y(0) \cos \gamma B t] \quad (7c)$$

These solutions may be verified by substitution. If the boundary conditions are that the transverse magnetization at time zero is $\mathbf{M}_0$ and the angle between $\mathbf{M}_0$ and the x axis at time zero is ϕ_0 then

$$M_x(t) = M_0 e^{-t/T_2} \cos(\gamma B t - \phi_0) \quad (8a)$$

$$M_y(t) = -M_0 e^{-t/T_2} \sin(\gamma B t - \phi_0) \quad (8b)$$

The form of these results is shown in Figure 3. The x and y components are exponentially damped monotonic oscillations that are 90° out of phase with each other.

4 THE ROTATING FRAME

NMR signals are detected not in the laboratory coordinate system, but in a system rotating at roughly the Larmor frequency ω_0 . Recall that NMR frequencies in modern laboratories are in the FM radio range—the range from a few to a few hundred megahertz. Let us think about FM radio for just a moment. We use radio to produce signals in the audio range of frequencies, to which our ears are sensitive—a few tens of hertz to a few kilohertz, the higher frequency depending upon our age (our ears become less sensitive to the higher frequencies as we get older). But when we tune in an FM station, we are tuning to frequencies in the megahertz range. What is going on here? A very simple explanation is that the 'information' in the audio range is 'carried' by a frequency

Figure 3 Bloch relaxation in a field along the z axis. The initial state is magnetization in the (x, y) plane

in the megahertz range by a process of modulation of the higher frequency with the lower, so that both frequencies are carried over the airwaves. When the signal that is broadcast from the radio station is received by our radio, we ‘tune it in’, which is in effect ‘demodulating’ the carrier from the kilohertz frequencies that are the interesting and desired information. An analogy might be a child seeing a group of children playing on a merry-go-round, but being unable to see what they are really doing because the merry-go-round is going around too fast. The children on the merry-go-round are simply a blur to the child on the ground. However, if the stationary child hops on the merry-go-round, he is in sync with the other children, and can easily see all they do without the complication of the rotation of the playground instrument. An exactly similar situation applies to demodulating a megahertz carrier from the carrier-plus-kilohertz information. The motion of the carrier is removed from the view of the system by demodulation, i.e., by transformation to the frame of the merry-go-round—the ‘rotating frame’. Let us develop the classical rule for this transformation with the help of some simple diagrams and a little calculus.

Consider a vector $\mathbf{A}$ fixed in a coordinate system (cs) rotating with angular velocity ω (in rad s^{-1}) about the z axis of the laboratory frame, as indicated in Figure 4 (for example, $\mathbf{A}$ might be a line painted on a top). The angular velocity vector ω is therefore parallel to the z axis of the laboratory frame. Let x, y, z label the laboratory cs, and x', y', z' the cs rotating about z with angular velocity ω such that in any time period δt the angular change is $\delta\phi = \omega \delta t$. As indicated in Figure 4, if $\mathbf{A}$ is fixed at an angle θ to the axis of rotation, as indicated in Figure 4(b), then the magnitude of the change in $\mathbf{A}$, $\delta\mathbf{A}$, is given by

$$|\delta\mathbf{A}| = |\omega| |\mathbf{A}| \sin\theta \delta t \quad (9)$$

So, relative to a fixed laboratory cs,

Figure 4 Geometrical representation of the transformation to the rotating frame

$$\lim_{\delta \rightarrow 0} \frac{\delta \mathbf{A}}{\delta t} = \frac{d\mathbf{A}}{dt} = \boldsymbol{\omega} \times \mathbf{A} \quad (10)$$

Note that equation (10) sets the direction of $\boldsymbol{\omega}$ relative to the direction of rotation.

Now suppose that $\mathbf{A}$, instead of being fixed in the cs that is rotating within the laboratory, is moving with respect to this rotating cs. For example, the rotating cs might be fixed in a child’s top that is turning, and the vector $\mathbf{A}$ might be fixed to an ant that happened to be on the top when it is set spinning, and is walking around on the top while it is spinning. Suppose this ant is walking on the top with velocity relative to the top $D\mathbf{A}/Dt$. Then, relative to the room in which the top is spinning,

$$\frac{d\mathbf{A}}{dt} = \frac{D\mathbf{A}}{Dt} + \boldsymbol{\omega} \times \mathbf{A} \quad (11)$$

The total motion is just the superposition of the two motions. Identifying the vector $\mathbf{A}$ as the magnetic moment $\mathbf{M} = \gamma \mathbf{L}$, we see that

$$\frac{d\mathbf{M}}{dt} = \frac{\gamma d\mathbf{L}}{dt} = \gamma \mathbf{M} \times \mathbf{B}_0 \quad (12)$$

or the rate of change in the rotating cs is

$$\frac{D\mathbf{M}}{Dt} = \mathbf{M} \times (\gamma \mathbf{B}_0 + \boldsymbol{\omega}) \quad (13)$$

Equation (14) has two important consequences: first, transforming to the rotating frame replaces $\mathbf{B}_0$ with an ‘effective’ field $\mathbf{B} = \mathbf{B}_0 + \boldsymbol{\omega}/\gamma$. The second, critical to this discussion, is that if $\boldsymbol{\omega} = -\gamma \mathbf{B}_0$ then $D\mathbf{M}/Dt = 0$, i.e., there is no motion relative to the rotating cs. An equivalent statement is that, relative to the fixed frame, the moment is precessing about the z axis with angular velocity ω_0 . This is just the result we inferred before: a magnetic moment in a field will precess about the field with Larmor precession frequency $\omega_0 = \gamma B_0$. It is easy to see that transformation to the rotating frame accomplishes two ends. First, the equation of motion in that frame is simplified; the moment is static in this frame. Second, it becomes clear inferentially that motion relative to the laboratory frame is precession about $\mathbf{B}_0$, a fact perhaps not immediately detectable from first observation of equation (3).

5 THE PULSE NMR EXPERIMENT: PULSE AND FOURIER TRANSFORM NMR

As we indicated in Section 4, the NMR signal is generated by a carrier operating at ω_0 , generally in the frequency range of tens of to hundreds of megahertz. The information content, which develops as a modulation on the carrier, is obtained by demodulating the carrier from the total signal. In pulse operation, a simple schematic of how this is done is shown in Figure 5. S is a switch, controlled by a pulse programmer. D is a signal divider. A mixer mixes signals at ω_1 and ω_2 , and produces a mixed signal at frequencies $\omega_1 \pm \omega_2$.

An idea of how this apparatus allows us to look at the response of the net magnetization associated with an ensemble of nuclear spins in a magnetic field, polarized initially in the z direction, parallel to the static magnetic field, and acted upon by a transient radiofrequency pulse is now discussed. To start, let us indicate schematically how we view the situation

Figure 5 Simple schematic of a pulsed NMR spectrometer

in the rotating frame, the frame of the demodulated signal, in which we mix the carrier frequency ω_0 with the carrier plus the information content, $\omega_0 + \delta$, to observe the signal oscillating at frequency δ from the frame of our observation. By adjusting the phase shifter in the reference phase arm of the spectrometer, we may swing our view around in the rotating frame to look anywhere in the (x,y) plane. Let us look in the y direction, as indicated in Figure 7(a) below.

At this point, it is necessary to consider the relation between the time and frequency domains in NMR. The reason for having to deal with this duality is that many modern NMR experiments utilize transient excitations to cause NMR, with the result that the observable is a transient magnetization varying with time: $I(t)$ (cf. Figure 3), an intensity versus time; i.e., a signal observed in the time domain. For many purposes—and most familiar to those who routinely deal with NMR as a tool for identifying chemical shifts—the most common representation of the desired information is a plot of intensity versus frequency. Therefore we must become a little familiar with how signals in the time and frequency domains relate to each other. A simple way to see this relation is to consider a simple sine wave $I(t) = \cos \omega_0 t$. A plot of this function appears as shown in Figure 6(a). Now, think for a moment what this signal must look like as a function of ω . This function is monotonic in the frequency ω_0 . It is a delta function at $\omega = \omega_0$. There is only one frequency in this signal, that of ω_0 . This plot of $I(\omega)$ versus ω is shown in Figure 6(b). The mathematical operation that transforms $I(t)$ to $I(\omega)$ is called a *Fourier transform*. We may symbolically write $I(\omega) = \mathcal{F}I(t)$. The inverse statement would be $I(t) = \mathcal{F}^{-1}I(\omega)$. At this point, it is not important what specific mathematical form is represented by the operator $\mathcal{F}$. It is only important to know that it exists and that, as we have seen above in thinking about how a sine wave is represented in the time and frequency domains, as a mathematical operator it is a lot less complex than the left hemisphere of our brain. The formalism of Fourier transforms and their physical applications is nicely discussed by Champeney.⁵

Now let us consider an ensemble of nuclear moments μ_k , which sum together to form a macroscopic moment $\mathbf{M}$. Since we are creating a classical description of NMR and the pulse experiment, we adopt the model that this moment at equilibrium in a static field $\mathbf{B}_0$ in the z direction is parallel to the z axis as shown in Figure 7(a). (For one treatment of

Figure 6 Relation between the time and frequency domain signals of a simple monotonic oscillation

Figure 7 The pulse NMR experiment: observation of the magnetization of the moment after a 90°_x pulse with observation along y in the rotating frame

the quantum mechanical description, see Chapter 2 of Gerstein and Dybowski.⁴⁾

We are now going to perform a pulse NMR experiment. First, we set the phase detector so that we are looking along the y axis. Then, as indicated in Figure 7(a), we apply a magnetic field B_1 , along the x axis for a time t_p such that the moment, which will precess about the new field B_1 with precession frequency $\omega_1 = \gamma B_1$, precesses by an angle $\omega_1 t_p = 90^\circ$, called the ‘tip angle’. (For a discussion and a graphical illustration of the setting of the reference phase and of the pulse width t_p , see Chapter 5 of Gerstein and Dybowski.⁴⁾ Note carefully the distinction between the phase angle, which we have designated by saying we are ‘looking’ along the x axis, and the tip angle. At the end of the time t_p , therefore, the moment has precessed about the x direction to finally lie along the y axis, as shown in Figure 7(b). At this point, it realizes that it is a nonequilibrium position *vis-à-vis* the static field, B_0 , so it proceeds to precess about B_0 as indicated in Figures 7(c)–(e).

Now, in the interest of clarity, we have been just a little bit too simplistic in our description at this point. There are some things that need to be said more carefully. For one thing, we have not specified that we are in the rotating frame, so

Figure 8 Time domain signal corresponding to observation illustrated in Figure 7

the vector B_1 , which in the laboratory is rotating about B_0 at frequency $\omega_0 = \gamma B_0$, is *relatively* motionless with respect to the x axis of the rotating frame. If we were to specify that we have set the carrier at exactly the Larmor frequency ω_0 , then at all times the x axis and the rf field vector B_1 would be parallel. However, if, as indicated in Figures 7(c) and (d), the carrier frequency is set at some small *offset* δ from the Larmor frequency of the nuclei in question then the axis of the rotating frame of the carrier frequency will rotate at δ with respect to the moment M . It is this rotation that is depicted in Figures 7(c)–(e). In addition, we have not said that during the application of the pulse, there will be some rotation of M about B_0 . If the frequency ω_1 is sufficiently large compared with the offset δ then we can neglect this rotation for the purposes of the present discussion—which we do. Then the NMR signal in the time domain is as shown in Figure 8. It will be an oscillation with period $2\pi/\delta$. A photo of such a signal due to protons in water is shown in Figure 9(a). If the resonance offset δ is set to zero, and we detect along the negative y axis, we will see the signal shown in Figure 9(b). The decay in amplitude of the signal with time is that associated with transverse relaxation, with time constant $1/T_2$, as discussed in Section 3.

6 CHEMICALLY SHIFTED SPECTRA

We finally come to the most commonly used fingerprint of the nucleus in an NMR experiment by a physical scientist, that of the *chemical shift*. Of course, these days, the most commonly used fingerprint of the nucleus familiar to the public is just its presence, as detected by NMR in the magnetic resonance imaging (MRI) scanning used by the medical profession to complement the use of the more biologically invasive X rays in medical imaging. It is an interesting side note that ‘MRI’ is not ‘NMRI’, because of the lack of education on the part of the public about the fact that ‘nuclear’ does not necessarily mean biologically damaging radiation of the type coming from the use of radioactive materials, and one of the major hazards experienced in the development of

Figure 9 Time domain signal of protons in water: (a) off resonance; and (b) on resonance after a 90°_x pulse with observation along $-y$ in the rotating frame

nuclear weapons. All matter consists of nuclei and electrons, among other particles, and most of them are not radioactive! So the ‘nuclear’ in NMR must not be confused with the implications to health that come along with the ‘nuclear’ of nuclear reactors! NMR does not mean ‘radioactive’. There *is* radiation in the NMR experiment, as we discussed above, in the FM radio range, but this radiation is like oak trees along the river bottoms in Iowa—common, and not hazardous to our health as applied in the NMR experiment.

The phenomenon of NMR, discovered in 1945 on protons, remained a physicists’ curiosity until 1950, when Procter and Yu⁶ noticed that in a solution of ammonium nitrate, NH_4NO_3 , there were two signals observed for the nuclide ^{14}N . These two resonances were incredibly close together in terms of the fractions with which we deal in our every day life. We think that if we can measure a weight to 0.1%, we are doing about as well as an analytical chemist can do. But the differences in resonance frequencies of nuclei in different chemical environments in molecules, e.g. the ‘ammonium’ chemical functionality compared with the ‘nitrate’ chemical functionality, is of the order of 0.000 01%, i.e., of the order of parts per million (ppm), rather than thousands of parts per million. In fact, in modern NMR spectrometers, we are able to detect differences of the order of thousandths of ppm, which is about equivalent to being able to see two cats sitting a foot apart on the Moon when viewed from the Earth. This is an incredibly delicate fingerprint in terms of the usual accuracy and precision of measurement in physical science, and has since its development commercially in the 1950s been the workhorse of quantitative and qualitative analysis for the working chemist dealing with liquid solutions. As just a simple

example of the power of the technique, we consider the protons in methanol, CH_3OH . Here there are two distinct chemical functionalities of hydrogen: those in the methyl group, CH_3 , and those in the hydroxyl group, OH . Recall the relation $\omega_0 = \gamma B_0$. In a molecule, a nucleus will experience not only the field B_0 from the magnet used in NMR, but also a *shift* in this field, designated as δ , the *chemical shift*, due to the different chemical electronic environments of the nuclei in methyl and in hydroxyl groups. For the protons in methanol, this shift will be about 5 ppm. Chemical shifts of hydrogen in organic molecules in solution commonly have a range of about 15 ppm of the resonance frequency. For example, protons in common organic molecules in a spectrometer operating at 500 MHz for ^1H will exhibit a chemical shift range of about $15 \times 500 = 7500$ Hz. Scalar couplings (see below) to other hydrogens and to carbons are characteristically around a hundred hertz. Resolution in commercial liquid state spectrometers is of order of a few tens of hertz, so hydrogen NMR on molecules in the liquid state supplies an easily detectable, well-resolved, and sensitive fingerprint for routine analysis.

In terms of what we can expect from the pulse NMR experiment, e.g. on ^1H in methanol, think a moment about what has just been said about chemical shifts. The two protons in methanol resonate about 5 ppm apart. Therefore, in a magnetic field, it is impossible to set the carrier frequency to be ‘on resonance’ with ‘protons’. If one sets the carrier to be on resonance with the methyl protons, one will be ‘off resonance’ by an amount δ from the hydroxyl protons, which will resonate, it turns out, at a higher frequency than the methyl protons. So an easy escape from this dilemma of where to set ‘resonance’ is just to choose a reference molecule, and refer all resonances to the nuclide of interest in that molecule. For hydrogen, this molecule is tetramethylsilane, $(\text{CH}_3)_4\text{Si}$ (TMS), and we say that nuclei resonate at so many ppm with respect to TMS. Since TMS also has carbon in the form of the NMR-active (not radioactive!) nuclide ^{13}C , and the NMR-active nuclide ^{29}Si , it is also the reference molecule now commonly used for NMR of both carbon and silicon.

So a pulse NMR experiment, for example on the two protons in CH_3OH , will result in two different sets of magnetic moments precessing about the static field. This means that now, instead of one frequency being observed in the time decay, we shall see two. A superposition of two frequencies is well known to ‘beat’ against each other, as is commonly heard in the tuning of a guitar by using harmonics. An example of such a beat signal is shown in Figure 10. This time domain signal contains two frequencies, so of course in the frequency

Figure 10 Slow beat pattern for chemically shifted protons observed in the rotating frame at a carrier frequency off resonance from both

Figure 11 NMR spectrum of two sets of chemically shifted protons; for example, the aromatic ring protons and the aliphatic ring protons in toluene, $\text{C}_6\text{H}_5\text{CH}_3$

Figure 12 Illustration of the relation between signals in the time and frequency domains. The width of the signal in the frequency domain is related to the damping constant T_2 in the time domain by $\text{fwhm} = 1/\pi T_2$

domain, there will be two peaks in the plot of $I(\omega)$ versus ω . The signal in the frequency domain is shown in Figure 11 for the aromatic and aliphatic protons in toluene. The general relation between the time and frequency domains is shown in Figure 12. Because of relaxation via processes associated with transverse and longitudinal relaxation, with time constants T_2 and T_1 , the time signal will not be an infinitely long oscillatory signal, as was first discussed in comparing time and frequency domains, but will be a damped oscillation. If the damping constant is, for example, T_2 then for many liquid samples, the relation between the damping in the time domain characterized by T_2 (meaning that the time signal will decay to $1/e$ of its value in a time T_2) and that in the frequency domain is that the *width* of the signal in the frequency domain will be

$\text{fwhm} = 1/\pi T_2$. So a signal in the time domain decaying to a third of its initial intensity in a time of 10 ms will have a linewidth in the frequency domain of $\text{fwhm} = 1/0.03 = 33$ Hz. If this signal is due to nuclei resonating 5 ppm apart at a frequency of 500 MHz, then the resonances will be $5 \times 500 = 2500$ Hz apart, which is pretty far compared with the linewidth of 33 Hz. We see, therefore, that under these conditions, two signals 60 Hz apart could be resolved, which is a resolution of $60/500 = 0.1$ ppm—and even this is not considered terribly good in really high-quality liquid state machines!

Not even mentioned in this brief review of the basics of the NMR experiment are fingerprints other than the chemical shift, fingerprints in the time domain, solids, quadrupolar nuclei, Thus, one can begin to understand why NMR is such an incredibly powerful and rich tool, both for the theorist and experimentalist, and for those outside of the immediate 'hard science' of the technique.

1 INTRODUCTION

Obtaining detailed structural information from NMR of solid samples is more complex than for liquids because of the absence of molecular tumbling in solids to average line-broadening interactions; hence, much greater probe bandwidths are required.^{1–4} The wide-line probe usually has spectral excitation bandwidth greater than 80 kHz (i.e., able to generate 90° pulses less than 3 μ s). To do this, it normally must withstand peak rf voltages in excess of 3 kV. Often wide-line probes are double-tuned (DT) to permit cross polarization (CP) and high-power decoupling for increased sensitivity and resolution. If $\pi/2$ pulse lengths below 2 μ s can be generated, multiple pulse line-narrowing techniques may be used to remove dipolar broadening,³ but this is generally possible only in single resonance probes where low inductance coils can be used effectively.

The most common solids probe is the cross polarization/magic angle spinning (CP MAS) probe, which adds high-speed sample spinning at the magic angle to the other capabilities of the DT wide-line probe for effective averaging of the chemical shift anisotropy (and perhaps dipolar broadening at very high speeds), thereby greatly improving resolution for spin- $\frac{1}{2}$ nuclei.⁵ Single resonance MAS probes can generate the short pulses needed for the combined rotation and multiple pulse spectroscopy (CRAMPS) line-narrowing technique for ^1H or ^{19}F . Large volume MAS rotors can achieve the rotational spin rate stability needed for slow MAS, where pulses are applied at precise rotor orientations to average out the anisotropic chemical shift broadening as with high-speed MAS, although sensitivity may be reduced. Commercially available extended variable temperature (X-VT) CP MAS probes permit experiments from 35 K to 650 °C.

When sufficiently large single crystals of the sample can be grown, high-resolution spectra and the chemical shift tensor can be obtained using a single crystal probe,⁶ which is similar to a wide-line probe but includes a goniometer and crystal orientation mechanism for rotating the sample about three perpendicular axes.

^aLoss tangent is approximate at 300 K, 30 MHz, and increases with temperature and frequency, especially in plastics and high- k dielectrics.

^bHigh purity, high density, with minor Y–Al–Mg–O glass phase.

Quadrupolar interactions require more complex motions for effective averaging.⁷ The dynamic angle spinning (DAS) probe allows the spinning axis to be changed rapidly while spinning the sample at high speeds. In another approach, known as double rotation (DOR), the sample is placed in a small spinner inside a larger spinner and spun about two intersecting axes simultaneously.

The short T_2 values (and often long T_1 values) in solids make sensitivity much lower than in liquids, and the requirement for high-power decoupling requires attention to efficiency at the proton frequency. In liquids probes, it is the sample coil that is most critical. For solids, it is the capacitors.

2 HIGH-POWER CAPACITORS

The special requirements of capacitors for NMR probes include the following: ultra-low magnetic susceptibility, high Q , high voltage, high current, ultra-low piezoelectric effects, and dielectrics devoid of unwanted NMR background signals. Losses in rf capacitors at a given frequency may be indicated by a capacitor quality factor Q_c , an effective series resistance [$\text{ESR} = (\omega C Q_c)^{-1}$], a loss tangent ($\tan \delta \cong \pi/Q_c$), or a loss factor, $k_d \tan \delta$, where k_d is the dielectric constant (relative permittivity). Direct current losses may be specified by a leakage resistance, but this usually has no relationship to R_p (the effective parallel resistance of a tuned circuit) above 1 MHz. Table 1 lists typical permittivity and loss properties of dielectrics frequently encountered in NMR probes.^{8–12}

Solids probes are usually designed for peak voltages of 2.5–4 kV, compared with ~ 1 kV for most liquids probes. Voltage breakdown strengths often tabulated for dielectrics are best ignored unless two important parameters are also specified: test material thickness and frequency. The frequency dependence is not easily characterized, but dc ratings of rf capacitors are typically four times the short-pulse rf ratings at 100 MHz. For very short pulses where heating is not much of a factor, the voltage rating at 10 MHz is typically only twice that

Table 2 Typical Dielectric Breakdown Voltages

Thickness (mm)	$V_B, k_d > 30$ (V)	$V_B, k_d < 10$ (V)
0.1	500	1000
0.5	1200	2200
3.0	3000	5400

at 500 MHz, but with long pulses the voltage derates at least as the $\frac{3}{2}$ power of the frequency above a cutoff that is a function of Q_c/C . Table 2 shows typical rf breakdown voltages, V_B , for several thicknesses of low- k and high- k dielectrics at 30 MHz. Above 50–100 V, V_B is a square root function of thickness and shows relatively little variation within the two classes of rf dielectrics listed.¹¹ Dry air has an ionization V_B comparable to that of high- k dielectrics, but arc voltage in monatomic gases (He, Ne, Ar) is less by a factor of at least five (more for large gaps) because of the absence of low-energy rotational and vibrational relaxation modes.¹³ The additional rotational modes in polyatomic gases usually increase the breakdown voltage, except in the case of ionic gases such as H_2O .

2.1 Ceramic Capacitors

The standard COG (ceramic oxide glass) rf capacitor specification (formerly type NPO) requires a temperature coefficient of less than ± 30 ppm and $\tan \delta$ below 0.001 for the range -55°C to 125°C . For moderate-power applications up to 300 MHz, the COG formulation usually consists of fine-grained baria–neodymia–titania systems or magnesium titanate prefired with 6 mol% calcium titanate, but they are also made from mixtures of neodymium carbonate, titania, and barium titanate. A two-stage firing is generally required for multilayer capacitors so that the final firing temperature can be kept below 1150°C to allow the use of Pd–Ag electrodes. The ceramic precursors are prefired at a high temperature, then reground and mixed with a powdered glass binder with matched thermal expansion such as 36% CdO, 23% Bi_2O_3 , 25% PbO, 5% ZnO, 5% B_2O_3 , 5% SiO_2 , 1% Al_2O_3 .⁹ Alternate layers of ceramic/glass and metallization slurry are built up by a screening or spraying process.

Porcelains (magnesium–aluminum–silicates) are often used in the UHF range for high-power capacitors below 15 pF. Corning Pyroceram 9606 consists mostly of cordierite ($2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$), with lesser amounts of cristobalite and various magnesium titanates. Its low thermal expansion can cause problems with the metallization. Forsterite ($2\text{MgO} \cdot \text{SiO}_2$) is electrically almost as good as Pyroceram, easier to produce, and easy to metallize, but has poor thermal shock resistance.

UHF high-power capacitors above 30 pF are usually based on strontium titanate, which is not piezoelectric but may contain piezoelectric barium titanate impurities. High-power rf capacitors are often coated with a sealing glass such as $2\text{PbO} \cdot \text{SiO}_2$ (550°C) to keep out moisture,⁸ as it facilitates silver migration in the presence of an electric field.

The magnetic properties of ceramic capacitors are unpredictable, as most ceramics are slightly diamagnetic (bismuth compounds are very diamagnetic), palladium is extremely paramagnetic, and ferromagnetic nickel barriers are sometimes used in the terminations. A number of manufacturers are by now quite familiar with the stringent requirements of

NMR/MRI capacitors and offer ‘nonmagnetic’ chip capacitors with 500–1000 V rating (a 2.5×3 mm cube), but it is always necessary to screen them for magnetism using a small magnet (a 2-mm cube of high-energy neodymium–boron–iron) suspended from a string. Also, nearly 1% of new capacitors may be noisy in a double resonance circuit as a result of microgaps between the electrodes or terminations and the dielectric.¹⁴ Premature breakdown may be initiated by surface tracking and moisture in solder rosin.

At least four manufacturers (JFD, ATC, Murata Erie, and Tansitor Electronics) offer 3-kV multilayer ceramic rf capacitors in roughly a $3.5 \times 10 \times 11$ mm³ package. The JFD capacitors have generally been found to have the highest Q , but the difference is often not important. Some of the best NMR ceramic capacitors (when available, but once discontinued) are the 2-kV UV10 and UV17 series ($3.3 \times 6 \times 8$ mm³) by Murata Erie, as they have very low magnetic susceptibilities and a 2-kV rating in a small package. Moreover, for typical circuit values (reactance above 100 Ω), Q_c is usually greater than 3000 for capacitance below 150 pF at frequencies at least up to 50 MHz, and Q_c is usually greater than 1000 up to 500 MHz.

2.2 Piezoelectric Acoustic Ringing

While acoustic ringing is seldom a problem in liquids probes because of the longer T_2 s and the effectiveness of the Patt acoustic suppression sequence,¹⁵ piezoelectric-induced acoustic ringing¹⁶ of capacitors can obscure signals in solids probes requiring short recovery times. Subjecting a capacitor with ferroelectric impurities to a dc electric field in excess of 1 kV mm^{-1} , as may occur in a voltage withstanding test or from asymmetric rf breakdown, causes domain alignment and imparts a net crystallographic piezoelectric orientation to the ceramic. The ferroelectric is said to be ‘poled’, and may exhibit acoustic ringing. The polarization of ferroelectrics can be annealed out by heating above the Curie temperature (130°C for BaTiO_3 ; 180 – 300°C for lead–magnesium–niobates), but they can easily become poled again.

Grain size is usually under $4 \mu\text{m}$ for rf power COG capacitors in the 10–30 pF range, in which case Rayleigh scattering will normally keep acoustic decay times under a few μs above 30 MHz. However, grain size may exceed $100 \mu\text{m}$ in high-voltage (HV) capacitors above 150 pF and occasionally in low-valued capacitors, resulting in reduced acoustic absorption and acoustic decay times greater than $10 \mu\text{s}$ at frequencies as high as 45 MHz. On the other hand, acoustic ringing in bulk metals from the Lorentz interaction is seldom a problem above 15 MHz.¹⁷

2.3 Variable Capacitors

The double rotation (DOR) probe shown in Figure 1 illustrates the use of three common types of variable capacitors (air, quartz, and pressurized gas) and 3-kV ceramic chip capacitors (attached to the left of the quartz variable near the center of the photo). The Johanson 5000-series nonmagnetic, air-dielectric, trimmer capacitor (one is mounted on the upper circuit board near the center of Figure 1, just to the right of the central support post) is typical of that used in most liquids NMR probes and the high-frequency (HF) channel in solids probes with capacitive voltage division. It consists

Figure 1 DOR WB probe (Doty Scientific, Inc.)

of an alumina ceramic housing supporting several concentric, silver plated brass cylinders at the 'hot' end; a precision screw mechanism adjusts a similar intermeshing arrangement at the mount end. The minimum radial air gap is under 0.1 mm, and breakdown occurs at 500–700 V when new. With use, alignment deteriorates, and the voltage rating decreases. Care must be taken to avoid dissolving the internal lubricants (which are essential for an acceptable lifetime) with cleaning solvents. The capacitors may be sealed, but this is inconvenient; hence, their voltage rating also decreases with altitude and humidity or high concentrations of monatomic gases. These variable capacitors are manufactured using 300 °C Pb–Ag solder between the alumina and brass body parts, and they tolerate repeated overvoltages.

Also shown in Figure 1 (near the center, on top of a gas variable capacitor, just left of the central support post) is the JMC 7584, quartz-dielectric, 0.8–10 pF, variable capacitor. Its 2.5-kV rf capability allows five-times the tuning range of the above air variables, as tuning range is generally proportional to $(CV^2)^{1/2}$. Defective silver plating on the piston or sleeve has occasionally been found to produce noise at lower voltages in double resonance circuits.¹⁴ Impurities in the brass base and piston of the JMC capacitor are not controlled as carefully as in a similar capacitor by Voltronics, but the JMC capacitor is more robust which simplifies certain capacitive voltage division arrangements,¹⁸ and the magnetism is acceptable unless it must be very close to the sample. These capacitors

have been used successfully up to 400 MHz. They may lock up at high temperatures from the piston expanding or at low temperatures from the lubricants freezing.

The single component most synonymous with solids NMR probes is the Jennings CHV1 N-45 gas variable capacitor—the 22-mm diameter ceramic cylinder on the left side of the main circuit board in Figure 1. It is pressurized with about six atmospheres of CO₂ and SO₂ in its minimum capacitance position and may be adjusted from 1.5 pF to 45 pF using a pushrod mechanism. It has a peak breakdown voltage V_B of about 3.5 kV near the low end of its range (~ 10 pF) but V_B increases to about 5 kV near the high end as the gas becomes more compressed. The ceramic-to-metal seals are slightly magnetic, but this is seldom a problem as they are normally more than 20 mm from the sample. These variables have been used successfully for tuning purposes up to 220 MHz. With proper layout, they are usable on the low-frequency (LF) channels of multituned circuits with 500 MHz HF. These capacitors tolerate repeated overvoltages and are usable from –20 °C to 100 °C. If the external mechanical stop is not set properly, they may be easily damaged by pushing the adjustment rod beyond the specified limit.

Teflon variables with very low magnetism are available from Polyflon and Voltronics in a variety of sizes and ratings similar to the three described above, but Teflon does not tolerate the brief, inadvertent overvoltages which are unavoidable in most laboratories.

3 SAMPLE COILS FOR SOLIDS

Almost all solids probes use solenoidal rf coils for higher filling factor and Q than saddle coils. Standard oxygen-free, high-conductivity (OFHC) electronic-grade copper wire (C10100, 99.99%) has acceptably low iron content (less than 25 ppm, typically 4 ppm) for most solids coils at high fields. Optimum space between wires is half the wire diameter¹⁹ or perhaps a little less. An enamel coating does not usually cause a background problem with carbon experiments, but it should be removed using warm sulfuric acid if proton experiments are planned.

High- Q circuits are usually preferred—except perhaps for wideline. Coil length-to-diameter ratio is not critical, but values between 1.0 and 1.4 (depending on available wire sizes) are usually best, except for MAS. Larger ratios (1.4–3.0) give better S/N for MAS (more sample for a given speed and lower dielectric losses), but some manufacturers use short coils to achieve shorter pulse lengths and higher decoupling fields. Coil forms help stabilize tuning but reduce both filling factor and maximum voltage before the onset of arcing. If used, they should be of low-permittivity dielectrics for minimal electric field gradients and arcing.

Special or custom wire may be obtained from MWS Wire Industries, Westlake Village, CA. Gold flash (0.3- μ m plating) is often applied to prevent copper sulfates and chlorides (which have a large positive susceptibility due to antiferromagnetism) from forming on the wire surface, but it is critical to specify that the common practice of first applying a nickel strike (to minimize diffusion into the copper) be omitted or the wire will be very magnetic. The gold flash degrades the Q by about 1%. Silver plating does not improve Q (because of unavoidable defects) and does not provide the same degree of

protection against corrosion—even when the plating thickness is increased to 3 μm . Silver and its compounds are quite diamagnetic but often contain paramagnetic impurities.

High-purity copper coils for high resolution are often plated with the proper thickness of iridium or rhodium to cancel the

diamagnetism of copper.²⁰ Palladium can also be used for this purpose if it is plated only on the side that will be the external surface of the coil (where there is little current flow) so that the Q is not spoiled. Table 3 lists various properties, including volumetric magnetic susceptibility χ_v , for materials commonly

found in NMR probes. The desired plating thickness for foil is that for which the algebraic sum of the product of thickness and χ_v for the different layers is zero.

4 WIDELINE

The initial instrumentation for solids NMR borrowed extensively from radar and UHF transmitter technology, using fixed-frequency transmission lines as circulators and magic-Ts to isolate the multikilowatt transmitter from the low-noise preamplifier.^{2,3} However, it was soon determined that it was not difficult to deal with the phase transients from Q s of 50–200—an order of magnitude higher than initially thought. Pulse rise times could be as much as one-third the pulse length without serious difficulties.²¹ Hence, several hundred watts were sufficient except perhaps for low- γ nuclei. The cost savings of moderate power transmitters and the shift from transmission line traps to lumped elements facilitated the commercial solids probe,²² which is usually required to be multinuclear and reasonably user friendly.

For proton NMR it is still beneficial to damp the Q to about 100 by coating the coil with tin–lead solder (as proton linewidths are large and sensitivity is enormous) but care must be taken not to trap rosin in the coating, or backgrounds will be seen. Also, experiments on other nuclides with very broad lines may benefit from moderate Q -damping if samples larger than 0.1 mL are being used, since the increased bandwidth simplifies data collection. A number of accelerated ringdown schemes have been proposed,^{2,23} but the method seeing more use today appears to be overcoupling^{24,25} because of noise, reliability, and magnetism problems associated with other methods. Moreover, the recent availability of linear prediction often obviates the need for active damping (see *Fourier Transform and Linear Prediction Methods*).

The unbalanced, capacitively matched DT circuit (see *Probe Design and Construction*, Figure 6) is usually used for wideline probes to simplify multinuclear tuning. The HF tuning coil L_H (which may be a capacitively shortened $\lambda/4$ coaxial transmission line) is chosen to have an inductance such that its untuned reactance would be between 25 Ω and 60 Ω at the HF. Lead inductance is minimized subject to VT, high voltage, and multinuclear constraints. The total series lead inductance is then typically 25–40 nH.¹⁴ Maximum B_1/V_T , where V_T is the maximum total circuit voltage, is obtained for coil inductance L_S half of the total circuit inductance, but a somewhat higher value is usually selected for improved LF sensitivity with some sacrifice in HF efficiency and a slight reduction in maximum B_1 .

Minimum 90° pulse lengths have typically been 3 μ s, but recent successful demonstrations of wideline ^2H Hadamard NMR²⁶ may have a major impact on single resonance solids NMR. In Hadamard NMR, the spin system response to the application of a large number of pseudorandom pulses with flip angles as small as 0.1° (mW, μ s pulses) at periods on the order of tens of microseconds can be transformed into the equivalent NMR response from a single high-power pulse. A Hadamard wideline probe should benefit from a low- Q (~ 5) saddle excitation coil in combination with a moderate- Q (~ 100) solenoid receive coil. SNR for Hadamard appears comparable to Fourier transform (FT). (See also *Stochastic Excitation*.)

5 MAGIC ANGLE SPINNING

In 1958, Raymond Andrew²⁷ and co-workers showed that high-speed sample spinning at the ‘magic’ angle of 54.7° could be an effective tool in averaging out dipolar broadening. However, the required rotational rates for abundant dipolar nuclei (35 kHz for ^1H) appeared impossible, and the technique was largely ignored²⁸ for nearly two decades until Stejskal and Schaefer^{4,5} showed that more realistic rotational rates (3–5 kHz), capable of averaging chemical shift anisotropy, combined with high-power decoupling to remove the ^1H dipolar broadening, could be extremely effective in obtaining high-resolution ^{13}C spectra from solid samples.

Andrew used a conical bearing/drive surface which eventually achieved speeds in excess of 10 kHz using helium gas.²⁹ This spinner was based on the classic ultracentrifuge work by Beams³⁰ and depended on the Bernoulli effect to hold the sample spinner close to the drive jets. The stiffness of such a bearing is extremely low, which results in low-frequency oscillations, precession, and instabilities. Moreover, angular accuracy of 0.3° is sometimes required in MAS, which is an order of magnitude beyond the capability of the conical Bernoulli–Beams bearing. Lippmaa,³¹ Veeman, Pines, Eckman, and others introduced the double bearing cylindrical rotor to circumvent these problems, and Doty and Ellis presented an approximate analysis of the cylindrical air bearing optimization.³² [Note that typographical errors resulted in equations (9) and (12) in the referenced article³² appearing twice. The second equation in each case is correct. The first should be deleted.]

The high-strength ceramics⁸ that have recently become available are required to obtain high sensitivity (from high filling factor) and high spinning speeds simultaneously. Silicon nitride³³ has the highest strength-to-mass ratio of any available ceramic, which allows the highest surface speeds with low-density samples; but zirconia has higher strength, better toughness, and fewer defects, making it the preferred material for heavier samples—except perhaps at very high fields or high temperatures. Most commercial MAS rotors and stators are ground and lapped (using precision diamond tooling) from partially stabilized zirconia (PSZ) or hot isostatic pressed (HIPd) Si_3N_4 . As a consequence, these items are rather expensive. The press-fit turbine caps are usually machined from Vespel, as polyether ether ketone (PEEK) has poor wear resistance despite its other desirable properties. Zirconia turbines may be attached to a zirconia rotor by thermal interference fit. Other high-strength plastics and ceramics as listed in Table 3 are also used for special thermal or background considerations. Fiber-optics spin-rate detection is normally provided to allow precise, synchronous pulsing for the total suppression of sidebands (TOSS) technique.³⁴

5.1 High-Speed Air Bearings

The high mass of ceramic rotors requires more attention to rotor resonances than was required in the earlier designs using plastic rotors.³⁵ For stability throughout a wide speed range, it is advantageous to have the high bearing stiffness that comes from tight radial clearances. However, as the clearance is reduced, bearing frictional heating becomes more severe; moreover, the possibility of a ‘crash’ increases. A crash may

occur in a hydrostatic bearing when the rotor moves close enough to the stator to cause extreme choking around the perimeter of the bearing nozzles on the proximal side, at which point the stiffness changes sign and the rotor is driven into the stator. Pockets or recesses at the orifice exit may eliminate this crash mechanism,³⁶ but the reduced response time adversely affects stability at very high speeds unless the pockets are very small.³⁷

Highest spinning speeds have been obtained with the design illustrated in Figure 2, which has achieved surface speeds in excess of the speed of sound at room temperature for rotor diameters from 5–14 mm. Half of the bearing gas exits over the ends of the rotor forming an axial thrust bearing at each end, while half exits out the center of the stator. Allowing the gas to flow axially inward as well as outward (nearly) doubles the bearing stiffness (by nearly doubling effective area) and was probably the most significant innovation in the spinner by Langer et al.³⁸ which achieved a 40% increase in surface speed over previous designs.

Optimum bearing radial clearance for controlling Taylor vortices³⁹ in the air bearing at moderate speeds is proportional to $(\mu^2 d / c^2 \rho^2)^{1/3}$, where μ is the gas viscosity, d is the rotor diameter, c is the velocity of sound, and ρ is the gas density. Optimum clearance r_c for the control of whirl instabilities with minimum friction at high speeds fits the following empirical equation for typical NMR spinners:

$$r_c \cong k T^{0.25} d^{0.4} \text{ (mixed units)} \quad (1)$$

where T is the gas temperature (K), d is the rotor diameter in mm, and k has an approximate numerical value of 0.0027 for nitrogen and 0.0035 for helium with units of $\text{K}^{-0.25} \text{ mm}^{0.6}$; it is necessary to take into account the strain that will occur even in ceramic rotors at top speeds: 0.1% and 0.15% for silicon nitride and zirconia, respectively. Smaller clearances than given by equation (1) may be used if the additional heating can be tolerated, and larger clearances may be used with large rotors if other measures are taken to control whirl instabilities. Optimum bearing hole size is such that bearing

Figure 2 Supersonic sample spinner (Doty Scientific, Inc.)

mass flow at 0.3 MPa with the rotor in place is 60%–85% of the mass flow with the rotor removed. Short bearing hole sizes normally range from 0.13 mm for 3.5-mm rotors to 0.28 mm for 14-mm rotors, but slightly larger long bearing holes work better for VT.

With very small rotors, the bearing clearance becomes extremely critical—partly for manufacturing reasons and partly for fundamental reasons. To appreciate the fundamental limitation, consider the conical resonance frequency,³² which is approximately proportional to the square root of the quotient of the bearing stiffness and the rotor mass near the end of the rotor. In order for this resonance to scale as $1/d$, the stiffness must be linear with diameter (since the mass is cubic with diameter), which requires the radial clearance to be proportional to the diameter if the pressure is constant. But clearance cannot be linear with diameter or frictional power density on the rotor surface becomes unmanageable with small rotors. Hence, Nature does not like small rotors, and it is in fact fortuitous that 5-mm rotors can achieve supersonic surface speeds (21 kHz) under optimum conditions with nitrogen bearing pressures of 0.5 MPa. While 3.5-mm Si_3N_4 rotors have occasionally reached 27 kHz, they are fraught with instabilities above 24 kHz which are exacerbated by the large, axial Bernoulli effects from poor turbine efficiency.

5.2 Radial-Inflow Microturbines

To achieve surface speeds above 240 m s^{-1} it is necessary to use microturbines in a symmetrical fashion so that axial reaction forces are precisely balanced at all speeds (unless helium drive gas is used), since the load capacity of the axial thrust bearings is quite limited.⁴⁰ The reduced-diameter radial-inflow microturbines used in Figure 2 achieve order-of-magnitude higher isentropic efficiency than the earlier Peltier microturbines by (a) controlling flow separation over the blades, (b) operating at lower tip speed, and (c) reducing exhaust swirl.⁴¹ Inlet and exit angles are not particularly critical, but axial clearance over the blades is—unless the turbine is designed for a very low reaction ratio. A vaneless radial-inflow supersonic diffuser may be used with the larger sizes to obtain supersonic, nonseparated flow at the rotor entrance. The microturbines on a 14-mm rotor have 28 blades with 10-mm tip o.d. and produce 25 W shaft power each at 40% isentropic efficiency at 6 kHz. The 2.5-mm o.d. microturbines on the 3.5-mm rotor have only 12 blades and achieve approximately 10% efficiency at 22 kHz. Unlike large turbines, substantial efficiency losses occur in the nozzles (even with the 14-mm spinners) because of boundary layer effects. For an excellent treatment of turbine theory and design, the reader is referred to the text by Wilson.⁴²

5.3 Radiofrequency Circuits

Most MAS work requires CP and/or high-power decoupling. Hence, the circuit is essentially identical to that described earlier for the DT wideline probe except that lead inductance may be a little larger,¹⁴ necessitating somewhat higher sample coil inductance for high sensitivity. Maximum B_1 is usually 30% less than expected of a similar DT wideline probe, but many wideline experiments are still possible

with an MAS probe. For large samples at high fields, it can be beneficial to balance the HF channel for more efficient decoupling—especially at high temperatures. A modified form of the standard ^1H – ^2H high-resolution balanced decoupler/lock circuit may be adapted to the high-power requirements of solids.⁴³

Wu and Zilm⁴⁴ showed that high rf homogeneity is much more important than originally recognized for efficient CP at high speeds and that variable amplitude proton B_2 can greatly improve CP efficiency in the presence of large rf inhomogeneity. Leifer⁴⁵ recently presented an elegant method of optimizing rf homogeneity for six- and 10-turn solenoids. Many software packages using numerical methods are now available for general field calculations and optimizations, and a few are capable of properly handling nonuniform surface current distributions.⁴⁶

Single resonance circuits can efficiently use very low inductance coils (e.g., two-turn, 6-mm, 18-nH coils) to achieve the short $\pi/2$ pulse lengths ($1.5 \mu\text{s}$) needed for multiple pulse techniques to average dipolar interactions of abundant ^1H or ^{19}F nuclei.⁴ When combined with sample spinning at several kHz to average chemical shift anisotropy, the technique is called combined rotation and multiple pulse spectroscopy (CRAMPS). High resolution in CRAMPS requires extremely high B_1 homogeneity. Since wide conductors and leads are required with low-inductance coils (to limit lead voltage, if not losses), the current locations are not known and the method of Leifer and related analytical methods cannot be used to homogenize the field. However, the most difficult technical problem in making CRAMPS probes is usually that of eliminating proton background signals from hydrogenous contaminants in Teflon and even Kel-F.

Triple resonance circuits have been used occasionally for more than a decade,⁴⁷ but the development of the powerful rotational echo double resonance (REDOR) technique⁴⁸ for accurate distance determinations from weak dipolar couplings has recently resulted in a large demand for triple resonance MAS probes. The circuit shown in Figure 3 uses an inductively coupled HF tank to permit multinuclear tuning at both the middle and the low frequency with high efficiency and excellent isolation on all ports.⁴⁹ It has been used successfully for ^1H up to 500 MHz, and can easily be extended to quad resonance experiments such as RETRO.⁵⁰ Fixed frequency triple resonance MAS probes for REDOR experiments are expected to be available soon at 750 MHz.

6 GONIOMETERS AND SLOW MAS

The earliest applications of NMR to solids involved the study of single crystals, as relatively narrow lines are observed without multiple pulse or high-speed spinning techniques. These studies are necessarily limited to materials that can be obtained in single crystals of sufficient size (usually several mm^3) for acceptable S/N. The method requires the ability to slowly and precisely rotate the crystal about three orthogonal axes while observing the anisotropic chemical shift. The standard method for the past two decades has involved gluing a small crystal into a three-sided, 4-mm ‘semicube’.⁶ (Similar probes with larger coils have rotated sealed tubes to study oriented liquid crystals.) The sample may then be inserted into a precision holder inside the sample coil for 360° rotation

Figure 3 Doubly broadband, triple resonance circuit (Doty Scientific, Inc.)

about an axis perpendicular to B_0 in small increments at which spectra are collected. The semicube is then removed and reinserted for rotation about a second axis, and the process is repeated again for the third axis. The crystal orientation with respect to the semicube holder is determined using X-ray crystallographic techniques.

The sample holder axis may be inclined at the magic angle to permit slow MAS, which is a method of addressing the spinning sideband problem by applying pulses precisely at 0° , 120° , and 240° . There is renewed interest in this technique for obtaining high-resolution spectra from large samples of dilute systems. (See *Magic Angle Turning and Hopping*.)

Rotation has usually been accomplished using precision aluminum or brass bevel gears, but worm gears, belts, and flexible shafts have also been used. The early versions used a manual goniometer, but a stepper motor under computer control is now common. A DT multi-X circuit is usually used.

7 VARIABLE TEMPERATURE (VT)

Most CP MAS probes operate from -120°C to $+160^\circ\text{C}$, but XVT CP MAS probes are available for wider temperature ranges, and several methods⁵¹ have been used to cool the drive gas and circumvent liquefaction problems in pressurized nitrogen. Gay⁵² optimized the conventional high-resolution sample tube spinner to obtain rotational rates sufficient for many MAS applications (over 3 kHz for 5-mm tubes) with the advantages of greater independence of the sample temperature and spinning characteristics and the ability to spin long, sealed glass tubes at the magic angle. The MAS design of Bartuska et al.⁵³ also provides clear separation between the VT and the bearing gas.

One manufacturer (Doty Scientific) uses a low-temperature and a high-temperature CP MAS probe, as pictured in Figure 4 along with a standard CP MAS probe, to cover the range from 35 K to over 900 K. In these probes, the electronics are maintained near room temperature and positioned close to the sample to allow multinuclear tuning without excessive lead losses, although lead inductance is increased by about 30 nH over the standard probes. Another manufacturer (Bruker) offers

Figure 4 VT CP MAS, low-temperature CP MAS, and high-temperature CP MAS probes

a gas-levitated, laser-heated wideline probe for experiments to 1200°C .⁵⁴ Attempts to provide CP MAS down to 6 K have proven too difficult for commercial success thus far, but a number of research groups^{55,56} have performed wideline NMR experiments in the 0.03–3 K range.

Figure 5 DAS probe with fixed coil and belt-drive spinner reorientation

8 DYNAMIC ANGLE SPINNING (DAS)

High-resolution NMR spectra can be obtained from quadrupolar nuclei if the sample spinning axis can be dynamically reoriented such that the time average of the second and fourth spherical harmonic functions vanishes.⁷ The dynamic angle spinning (DAS) probe allows the spinning axis to be rapidly changed while spinning the sample at high speeds to accomplish the required averaging. One early design used

a pneumatic system to switch between two fixed angles, but a high-performance servo motor and precision encoder are now standard, as programming flexibility is needed to experiment with the various ‘magic angle pairs’ such as $[0^\circ, 63.43^\circ]$, $[30.56^\circ, 70.12^\circ]$, and $[37.38^\circ, 79.19^\circ]$.⁵⁷

Two basic approaches have been used: moving coil and fixed coil. The moving coil design has the rf coil mounted on the spinner stator and attached with flexible leads or sliding contacts.⁵⁸ The fixed coil design uses a small spinner assembly that can be rotated perpendicular to its spinning axis inside a large rf coil that is perpendicular to the external field and coaxial with the reorientation axis.⁵⁹ The first commercial DAS probes used a moving coil, but it was abandoned in favor of the fixed coil because of lead failures, as most DAS experiments are two-dimensional and require millions of flips. The fixed-coil design has inherently poor filling factor, but special spinners and coils are being developed to minimize this drawback.

High-torque, low-inertia servo motors with optimized linkage should permit axis reorientation under 5 ms if the air bearings supporting the sample rotor have sufficient stiffness and load capacity; but control limitations, linkage compliance, and structure vibrations have often resulted in settling times of 25 ms or more.⁵⁹ The currently available commercial DAS probe shown in Figure 5 uses a 21-mm diameter rf coil, 8 mm long, and offers a choice of three interchangeable sample spinners: 8.6-mm diameter by 12 mm; 7-mm diameter by 13 mm; and 5-mm diameter by 14 mm. The shortest reorientation times thus far with 8.6-mm rotors are about 15 ms. Half that time may be possible with the 5-mm rotors, but the filling factor is very small. One of the factors contributing to the engineering difficulties is that the motor must be positioned well below the magnet to operate properly, which requires a rather long drive linkage that still must allow easy insertion of the probe into the magnet. The other major technical problem is that rotors with small aspect ratio (length-to-diameter ratio) are required for good filling factor, but a large aspect ratio is needed for bearing stability during rapid reorientation.

9 DOUBLE ROTATION (DOR)

In the DOR technique, the sample is placed in a small spinner inside a larger spinner and spun about two intersecting axes simultaneously to accomplish the time averaging needed to remove dipolar and quadrupolar interactions. It usually comes as a surprise to the uninitiated that such a feat would be possible at high speeds, even though most have observed a football traveling through the air executing free precession—spinning about two axes simultaneously with no significant external torques acting upon it.

The requirement for no net torques on the inner rotor is given by the following:

$$f_1 = \frac{f_2(I_T - I_A) \cos \theta_2}{I_A} \quad (2)$$

where f_1 is the frequency of the inner rotor, f_2 the frequency of the outer rotor, I_A the *axial* moment of inertia of the inner spinner (rotor, sample, caps), I_T the *transverse* moment of inertia of the inner spinner, and θ_2 is the angle of the inner rotor with respect to the axis of the outer rotor.⁶⁰

In practice, the outer rotor is always inclined at the dipolar magic angle, 54.7° , and θ_2 is 30.56° . For stability, (a) f_1 must be a few per cent larger than given by the above, (b) the center of mass of the inner rotor must lie precisely on the axis of the outer rotor, and (c) the outer rotor must be dynamically balanced when the inner rotor is removed. The highest double rotation rates thus far are approximately 1800 Hz outer and 7000 Hz inner for 0.1-mL samples. The outer spinner assembly of a DOR spinner is shown in Figure 1, inclined at 54.7° . (The braid-reinforced lines entering each end of the assembly supply air to the inner spinner.)

1 INTRODUCTION

Nuclear magnetic ordering (NMO), that is, the spontaneous transition of nuclear magnetic moments towards a magnetic ordered state under the effect of their mutual interactions, has long been a dream in the mind of reputedly ‘unrealistic’ physicists. This ‘unrealistic’ goal has become a reality during the last few decades. The reason why such an endeavor has long been considered a chimera can be understood as follows. Let $\hbar\Delta$ be the typical energy span of the interspin interactions. As an order of magnitude, ordering will take place below a critical temperature T_c such that

$$k_B T_c \approx \hbar\Delta \quad (1)$$

In the case of electronic spins, their mutual interactions are often Heisenberg interactions, which are nonmagnetic in nature: they are simply the mathematical expression of the difference between the electrostatic energies of a spin pair in the (orbital) symmetric and antisymmetric states. By virtue of the Pauli principle, an orbital state of a given symmetry corresponds to a spin state of opposite symmetry, so that the total state is antisymmetric. This is the reason why this interaction of purely electric orbital origin can formally be expressed as an interaction between the electronic spins. For many electronic spin systems, this interaction is so large that the critical temperature T_c is in the range 10^2 – 10^3 K (it is a notorious fact that permanent magnets exist at room temperature). In the case when the electronic spin–spin interactions are purely magnetic dipole–dipole interactions, the critical temperature T_c is much lower: of the order of 1 K. Magnetic moments of light nuclei in insulators also experience purely magnetic dipole–dipole interactions. Since these interactions are proportional to the square of the magnetic moments, and since nuclear moments are roughly three orders of magnetic smaller than electronic moments, it can be surmised from the start that the critical temperature for the onset of nuclear magnetic ordering lies at best in the microkelvin range, a range that for a long time appeared desperately out of reach of experiment. Indeed, the span of orbital energies is so much larger than this energy range (remember that $1\mu\text{K} \sim 20\text{kHz} \sim 10^{-10}\text{eV}$) that the heat capacity of solids is negligibly small at such temperatures, which raises formidable problems for extracting heat from the

sample so as to lower its temperature further, without even mentioning the problem of transferring the lattice temperature to the nuclear spins. The solution to this Gordian knot problem arose from the realization that, in order to produce nuclear magnetic ordering, it is not necessary to impart such low temperatures to the lattice: it is sufficient to cool the nuclear spins themselves. This implies that one can find conditions where spins and lattice may have different temperatures, and do not thermally mix over macroscopic time spans, and furthermore that one has means of imparting sufficiently low temperatures to the nuclear spins. There are two possibilities to meet these two conditions, which are described in *Low Spin Temperature NMR*. In one of them, practised in our laboratory, one uses insulators composed of light nuclei and performs the nuclear cooling in two successive steps: dynamic nuclear polarization (DNP) followed by nuclear adiabatic demagnetization.^{1,2} At low temperature (and in high field), the spin–lattice relaxation time T_1 is so long that waiting for nuclear thermal equilibrium would be exhaustingly time-consuming—whence the use of DNP—whereas this very length of T_1 ensures that, after demagnetization, the nuclear temperature can remain much lower than the lattice one over extended periods (a few minutes to several hours, depending on the samples), much longer than the time of order T_2 required to reach an internal equilibrium described by a spin temperature. As is well known in the NMR community, several options are open. One may demagnetize the spins to actual zero field, in which case the spin–spin interactions are the full dipole–dipole interactions. One may also demagnetize the spins in the rotating frame, by an ADRF (adiabatic demagnetization in the rotating frame), in which case the spin–spin interactions are the secular dipolar interactions, whose form depends on the orientation of the external field with respect to the crystal axes. Furthermore, the sign of the spin temperature may be chosen at will to be either positive or negative. The ordered state for $T \rightarrow +0$ is that of minimum energy, whereas that for $T \rightarrow -0$ is the state of maximum energy. The cooling of the nuclear spins by ADRF in high field has two consequences (advantages?). Firstly, the double freedom of field orientation and temperature sign makes it possible, with one and the same sample, to explore a whole series of different orderings—a bonus as regards physical interest. Secondly, the presence of the large external field makes it possible to study the system by NMR—a bonus for the ‘Encyclopedia of NMR’. This approach enabled us to observe nuclear antiferromagnetism in CaF_2 in 1969,³ as well as to perform many other NMO studies in the following years (see, e.g., Chapter 8 of Abragam and Goldman⁴).

The second method^{5,6} of nuclear cooling has been practised with metals. In very high field and at very low temperature (in the millikelvin range), the thermal equilibrium nuclear polarization is high, and the efficient Korringa mechanism for spin–lattice relaxation enables the nuclear spins to reach thermal equilibrium in a reasonable time. In the subsequent adiabatic demagnetization (in two stages), the final metallic sample, on which NMO is to be produced and studied, is thermally isolated (by a surrounding vacuum and superconducting thermal barrier with preceding demagnetization stage). At very low temperature, the specific heat of the conduction electrons is so low that, although much hotter than the nuclear spins, the former are unable to heat the latter. NMO has been obtained in actual zero field in metals since 1979.^{6,7} It turned out that in

most metals studied, the spins were ‘frustrated’ with respect to dipolar interactions, and that the ordering was determined in a large part by small RKKY interactions. This frustration, associated with the small value of the nuclear gyromagnetic ratios, resulted in very low critical temperatures, and it enabled the authors to beat ‘the world record of low temperature’. In fact, as explained in *Low Spin Temperature NMR*, what counts is not so much temperature as entropy. The spin frustration in metals resulted in ‘world-beating records’ of low transition entropy.

The purpose of this article is to give an overall description of the thermodynamic approximations used for the study of nuclear magnetic ordering. It is limited to those methods used in our laboratory to study pure dipolar magnetic ordering in high field. Rather than developing heavy calculations whose description can be found elsewhere,^{4,8,9} we have chosen to insist on the principles and ideas behind these calculations.

2 LOCAL WEISS FIELD. PREDICTION OF ORDERED STRUCTURES

We consider for simplicity, and as a typical example, systems with equivalent nuclear spins, such as ¹⁹F in CaF₂. The well-known form of the secular dipole–dipole Hamiltonian is

$$\hat{\mathcal{H}}'_D = \frac{1}{2} \sum_{ij} A_{ij} (2\hat{I}_z^i \hat{I}_z^j - \hat{I}_x^i \hat{I}_x^j - \hat{I}_y^i \hat{I}_y^j) \quad (2)$$

where

$$A_{ij} = \frac{1}{2} (1 - 3 \cos^2 \theta_{ij}) r_{ij}^{-3} \quad (3)$$

The essence of the mean field approximation is to neglect short-range correlations, that is to write

$$\langle \hat{I}_\alpha^i \hat{I}_\alpha^j \rangle \approx \langle \hat{I}_\alpha^i \rangle \langle \hat{I}_\alpha^j \rangle \quad (4)$$

The energy associated with the Hamiltonian of equation (2) can then be written as

$$\langle \hat{\mathcal{H}}'_D \rangle = \frac{1}{2} \sum_{i,j} \omega_{ij} \cdot \langle \hat{\mathbf{I}}_i \rangle \quad (5)$$

where the local mean field has components

$$\omega_{iz} = \sum_j A_{ij} 2 \langle \hat{I}_z^j \rangle \quad (6a)$$

$$\omega_{ix} = - \sum_j A_{ij} \langle \hat{I}_x^j \rangle \quad (6b)$$

$$\omega_{iy} = - \sum_j A_{ij} \langle \hat{I}_y^j \rangle \quad (6c)$$

This mean field (in a nonlocal form, as seen later) was introduced phenomenologically by Pierre Weiss to describe ferromagnetism. In most cases, it is due to Heisenberg interactions, and it is dubbed the ‘molecular field’. In the present case, it is actually magnetic, and has nothing to do with molecules. This is why we prefer to call it the ‘Weiss field’.

In this picture, the spins are treated as independent particles evolving in a self-consistent field, and their entropy has its standard form. For spin- $\frac{1}{2}$, for instance, it is

$$S/k_B = \sum_i \{ \ln 2 - \frac{1}{2} [(1 + p_i) \ln(1 + p_i) + (1 - p_i) \ln(1 - p_i)] \} \quad (7)$$

By maximizing

$$-\beta F = S - \beta \langle \hat{\mathcal{H}}'_D \rangle \quad (8)$$

where

$$\beta = (k_B T)^{-1} \quad (9)$$

is the ‘inverse temperature’, one obtains

$$|\langle \hat{\mathbf{I}}_i \rangle| = I B_I(|\beta \omega_i|) \quad (10)$$

which, for spins $\frac{1}{2}$, yields, more precisely,

$$\langle \hat{\mathbf{I}}_i \rangle = -\frac{1}{2} \frac{\omega_i}{|\omega_i|} \tanh \left(\frac{\beta |\omega_i|}{2} \right) \quad (11)$$

Remark. What one learns in thermodynamic courses and books is that the stable state of a system is that which minimizes its free energy

$$F = E - TS \quad (12)$$

The basic facts are, however, that

1. an isolated system has a constant energy,
2. its stable state is the most probable one—that is, that of maximum entropy.

From mathematics, we know that we can replace this problem of constrained maximum by an unrestricted one through the use of a Lagrange multiplier; that is, we look for the unrestricted maximum of $S - \beta E$, which is identical with equation (8)—an equation that can be used to define F . The multiplier β is later identified with inverse temperature. In usual systems, the temperature T and therefore β are always positive, so that if $-\beta F$ is maximum then the free energy F is minimum. For spin systems at negative temperature, stability corresponds to F maximum—a result that has often been found difficult to swallow by outsiders. NMR, spin temperature theory and nuclear magnetic ordering have compelled us not to content ourselves with standard formulas from standard books, but to return to the very roots of statistical thermodynamics.

There are two ways to proceed. The approach of Luttinger and Tisza¹⁰ (or more precisely a ‘trick’ found in this reference) considers the case of zero temperature, a case where

1. the entropy vanishes, so that stability corresponds to E minimum or maximum, for $T \rightarrow +0$ or $T \rightarrow -0$, respectively;
2. all spins are fully polarized:

$$\forall i, \quad \langle \hat{\mathbf{I}}_i \rangle \langle \hat{\mathbf{I}}_i \rangle = I^2 \quad (13)$$

Again, we are confronted with an extremum problem with constraints, which can be solved by the method of Lagrange multipliers—as many as there are spins in the sample, say N . In this form, the problem is well nigh intractable. The ‘trick’

of Luttinger and Tisza is to replace the N constraints by a single one:

$$\sum_i \langle \hat{I}_i \rangle \langle \hat{I}_i \rangle = N I^2 \quad (14)$$

which restricts the requirements to only one Lagrange multiplier λ . The solution turns out to be

$$\omega_i = \lambda \langle \hat{I}_i \rangle \quad (15)$$

Owing to the form in equations (6a)–(6c), for ω_i , it is evident that one must use Fourier transforms, that is

$$\omega(k) = \lambda \langle \hat{I}(k) \rangle \quad (16)$$

This system has N solutions, with values of λ associated with Fourier transforms $A(k)$ of the dipolar coefficients A_{ij} either $2A(k)$ for ordering parallel to Oz or $-A(k)$ for ordering perpendicular to Oz .

The stable solution at T positive (respectively negative) corresponds to the minimum (respectively maximum) value of λ . If the solution thus determined happens to satisfy the N constraints in equation (13), it can be shown that it is the correct solution.

In the approach of Villain,¹¹ one considers the immediate vicinity of T_c , where the polarizations are vanishingly small, so that one can use a linear expansion for the Brillouin function. Equation (10) is then of the same form as equation (15), with $\lambda \propto T_c$. It can be shown that the stable structure is that for which $|T_c|$ is maximum. This is the same criterion as for the Luttinger and Tisza method, and the solutions are the same. For the ‘good’ L–T solutions, all $|\langle \hat{I}_i \rangle| = I$. The corresponding $|\langle \hat{I}_i \rangle|$ near T_c are very small, but all equal; i.e., all Weiss field coefficients have equal modulus. It is likely that the solution at both ends, $T = T_c$ or $T = 0$, remains the same at intermediate temperatures, which has been backed up by experiment in all cases investigated. These kinds of solutions to the problem of the stable structure, where all $|\langle \hat{I}_i \rangle|$ have equal temperature-dependent values, have been called ‘permanent’ solutions, because, to within a scaling of $|\langle \hat{I}_i \rangle|$, they remain the same through the whole temperature range of ordering.

Things may be different when there are different kinds of spins: spins of different species, such as in LiF or LiH, or spins with different environments, such as ^{19}F in KMgF_3 . The reason is that at zero temperature, it is natural to use different Lagrange multipliers λ_α for the different kinds of spins I_α , whereas close to the transition, there is one transition temperature common to all spins, so that the equations at both ends are not the same. If the stable states at $T = T_c$ and at $T = 0$ are not the same, one may expect a first-order transition at an intermediate temperature. This example shows that both approaches—Luttinger–Tisza and Villain—are useful, and complement each other.

There is a case where Villain proves better than L–T: it is for detecting stable quasi-permanent structures. A case at hand is that of the so-called ‘ferrosandwich’ in CaF_2 , at negative spin temperature and with the field orientation in an angular domain around $[111]$. The maximum of λ (which determines the stable structure) corresponds to values of k that are small (i.e., k^{-1} much larger than the interatomic distance a), and parallel to Oz . However $\langle \hat{I}_z(k) \rangle \neq 0$ corresponds to a sine modulation of the spin polarization—definitely not a

permanent solution. Although it is acceptable near T_c , the question arises as to how it will evolve at lower temperature. The solution arose from the fact that $\lambda(k)$ is degenerate for all k in a given direction as long as their modulus is small. One can then combine small- k components parallel to Oz , until one obtains a ferromagnet with domains in the form of thin slices perpendicular to the external field, with polarizations alternatively parallel and antiparallel to the field. The limitation $ka \ll 1$ shows up in the fact that the transition between the domains is not infinitely sharp: the domain wall has a finite thickness, which should depend on temperature. Approximate models⁹ show that this thickness should be small, which is substantiated by experiment. Historically, we began with the L–T approach and missed completely the prediction of this structure. It was the observation by W. Th. Wenckebach (then on a visit to our laboratory) and J. F. Jacquinot of a splitting of the ^{43}Ca NMR signal, after ADRF at $T < 0$ and with $\mathbf{B}_0 \parallel x[111]$, that let the light be and rendered evident the merit of the Villain method.¹¹

3 WEISS FIELD AND BEYOND

3.1 The Weiss-Field Approximation

Once the stable, permanent structure has been determined by the above methods, one can use the Weiss-field approximation at temperatures intermediate between 0 and T_c , through its main result—the relation in equation (10) between spin polarization and Brillouin function—with, however, both a simplification and an extension. The simplification is that since in zero effective field all Weiss fields have the same modulus, there is only one Weiss field coefficient, and the number of equations required to analyze the properties of the ordered state is small. The extension is to the case when the ADRF is not stopped at exact resonance, and/or when an rf field is present, so that the spins experience both an effective field and a Weiss field.

The Weiss-field approximation can be combined with intuition to guess, and then check by calculation, the existence of more complex structures. We take as an example CaF_2 demagnetized at $T < 0$ with the field parallel to $[100]$. Theory predicts in zero field the occurrence of antiferromagnetism, with two sublattices of opposite polarizations. A distinctive property of antiferromagnets is that the lower the temperature (in absolute value), or else the lower the entropy, the lower is the parallel susceptibility. This means that in a longitudinal magnetic field (produced by adiabatic remagnetization), the bulk nuclear magnetization along the field remains small. There is no possibility of transition to a spin-flop phase as in Heisenberg antiferromagnets, because of the anisotropy of $\hat{\mathcal{H}}_D$. Above a threshold magnetic field, it is more advantageous for the system (i.e., it increases its free energy—remember, $T < 0$!) to shift to a paramagnetic state with all spin polarizations parallel, so as to sacrifice Weiss-field energy at the benefit of Zeeman energy. That things behave differently can be surmised by the following intuitive argument. Whereas in the L–T approximation, the state of highest energy is the antiferromagnetic state referred to above, the next ‘best solution’ is the ferrosandwich, with thin slices of polarizations alternatively parallel and antiparallel to the external field. The

latter has a reasonably high parallel susceptibility. Whereas in zero effective field, the domains of opposite polarizations have equal widths and the bulk magnetization vanishes, in the presence of a longitudinal effective field, this magnetization can easily grow through the motion of the domain walls, so as to favor the domains with magnetization antiparallel to the field against those of opposite magnetization (This is what is actually observed in the ferrosandwich structures, and serves to ascertain their nature.) It would be nice to maximize the free energy by a compromise whereby neither the Zeeman energy nor the antiferromagnetic Weiss-field energy would be sacrificed, by a combination of best and second best solutions in the form of a structure consisting of thin slabs perpendicular to the field, retaining some antiferromagnetic character, but having different bulk polarizations. By trial-and-error Weiss-field-based calculations, the best solution consists of such a structure indeed, where one type of slices is antiferromagnetic with small parallel magnetization, and the other is paramagnetic with all individual spin magnetizations antiparallel to the effective field. The relative volumes of these two types of slices are functions of the field. This was experimentally investigated by following, as functions of field and entropy, the relative intensities of the two NMR lines of ^{43}Ca , differently shifted by the different mean fields at their sites in the two types of domains. The striking agreement of the results with theory proves that this guess was the good one.

All and all, the Weiss-field approximation yields on the average predictions in agreement with both experiment and logic—but only at sufficiently low entropy. Close to the transition, it is totally inadequate, and some account of short-range correlations is definitely required. We describe below some of the approximations that we have used.

3.2 The Heisenberg Approximation

It is probably the first attempt made to account partly for short-range correlation effects on ferromagnetism,¹³ devised by Heisenberg (shortly after introducing exchange interactions, that provided the explanation for the huge molecular fields required in the Weiss model).

The idea of Heisenberg was to consider the subspace with total angular momentum S' for the N individual spins of the sample. It is easy to calculate within this subspace the first and second moments of the exchange energy. It is then assumed that, within this subspace, the density of states is a Gaussian function centered on the first moment, of width determined by the (reduced) second moment. This enables one to calculate the partition function, whence all properties of the system.

We have tried to modify this method slightly, so as to adapt it to such cases as antiferromagnetism, as follows. For an antiferromagnet with sublattices $\mathcal{A}$ and $\mathcal{B}$, we have calculated the first and second moments of the secular dipolar energy in a subspace with well-defined sublattice polarizations, i.e.,

$$\sum_{i \in \mathcal{A}} I_z^i = \frac{1}{2} N L p_A, \quad \sum_{\mu \in \mathcal{B}} I_z^\mu = \frac{1}{2} N L p_B \quad (17)$$

and we have similarly assumed a Gaussian density of states within this subspace. It should be noted that for ferromagnetism, this variant differs notably from the Heisenberg approach.

We never actually used this modified Heisenberg approximation, because we soon realized that the Kirkwood approximation, to be described next, was better: to the lowest order of short-range correlations, it yielded results identical with the present approach, but it also yielded a general procedure to push the approximation further.

3.3 The Restricted Trace Approximation

We illustrate the principle of the restricted trace approximation^{14,15} for the case of an antiferromagnet of spins $\frac{1}{2}$. Each sublattice $\mathcal{A}$ and $\mathcal{B}$ has an equal number $\frac{1}{2}N$ of spins. All static properties of the system can be deduced from the knowledge of the partition function:

$$\mathcal{Z} = \text{Tr}\{\exp(-\beta \hat{\mathcal{H}})\} \quad (18)$$

We choose as a basis the eigenstates of both:

$$\hat{I}_z^{\mathcal{A}} = \sum_{i \in \mathcal{A}} \hat{I}_z^i, \quad \hat{I}_z^{\mathcal{B}} = \sum_{\mu \in \mathcal{B}} \hat{I}_z^\mu \quad (19)$$

and we split the Hilbert space into subspaces corresponding to the different eigenvalues of $I_z^{\mathcal{A}}$ and $I_z^{\mathcal{B}}$:

$$\langle \hat{I}_z^{\mathcal{A}} \rangle = \frac{1}{4} N p_A, \quad \langle \hat{I}_z^{\mathcal{B}} \rangle = \frac{1}{4} N p_B \quad (20)$$

The trace in equation (18) is a sum of partial traces:

$$\begin{aligned} \mathcal{Z} &= \sum_{p_A, p_B} \text{Tr}'\{\exp(-\beta \hat{\mathcal{H}})\} \\ &= \sum_{p_A, p_B} \mathcal{Z}'(\beta, p_A, p_B) \end{aligned} \quad (21)$$

We then assume that the restricted traces $\mathcal{Z}'(\beta, p_A, p_B)$ exhibit sharp maxima for p_A and p_B equal to the sublattice polarizations in the ordered state. To within a correction of order $\ln N$, negligible compared with N in the limit as $N \rightarrow \infty$, we have

$$\ln \mathcal{Z}(\beta) \approx \ln \mathcal{Z}'(\beta, p_A, p_B) \quad (22)$$

The procedure is to calculate $\mathcal{Z}'(\beta, p_A, p_B)$ and to choose the polarization values from the condition of maximization:

$$\frac{\partial}{\partial p_A} \ln \mathcal{Z}' = \frac{\partial}{\partial p_B} \ln \mathcal{Z}' = 0 \quad (23)$$

In practice, $\ln \mathcal{Z}'(\beta, p_A, p_B)$ can be calculated in the form of a power expansion in short-range correlations within the $\{p_A, p_B\}$ subspace, proportional to increasing powers of β . Using such limited expansions in the rigorous relations (78) and (79) of *Low Spin Temperature NMR* yields approximations of various orders to the properties of the state. It can be shown that, to the lowest order of approximation for short-range correlations, this method yields results identical with those of the Heisenberg approximation of the preceding subsection.

The advantage of the restricted trace is that the extension of the approximation to higher orders is obvious, even if not easy in practice. We have used approximations up to the third order.

3.4 The ‘Physical Model’

This home-made model was devised *à propos* the study of transverse rotating helical magnetic ordering^{16,17} in CaF_2 , at $T > 0$, and with the field orientation in the vicinity of the [111] direction. It is much simpler to explain it for the case of the ferrosandwich, which occurs for similar field orientations, but at negative temperature. Let us consider the case when the field is parallel to [111]. For such an orientation, the secular dipolar interaction of a given ^{19}F spin with its nearest neighbors vanishes, because $\cos\theta = \sqrt{1/3}$ in equation (3). It is possible to imagine a relative orientation of its next-nearest neighbors that would maximize the local field it experiences, but this structure is not translationally invariant. The ‘frustrated’ spins then take advantage of the long range of dipolar interactions: they sacrifice the mean field from close neighbors at the benefit of that originating from distant nuclei. Indeed, consider a thin pancake normal to $\mathbf{B}_0$ with all ^{19}F spin polarizations parallel to $\mathbf{B}_0$. We can draw a sphere around a given spin and compute the mean field it experiences as the sum of the contributions from the spins inside the sphere and those outside. The first one vanishes for the sc lattice of ^{19}F in CaF_2 . As for the second one, it is indeed maximum for that particular domain shape, as is known from classical magnetostatics. The nature of the structure can be deduced by different, and more systematic means (Section 2), but the important lesson of present use is that the Weiss field is due to distant spins. It is known from general arguments that distant spins do not experience short-range correlations, i.e., that

$$\langle \hat{I}_z^i \hat{I}_z^j \rangle \approx \langle \hat{I}_z^i \rangle \langle \hat{I}_z^j \rangle \quad (24)$$

Let us now isolate by thought a sphere of homogeneous spin polarizations, of radius large enough compared with the interatomic spacing that surface effects are negligible. Then the mean field experienced by all spins of the sphere is due to distant spins for which equation (24) holds. As a consequence, the field does not differ qualitatively from that produced by an external magnet. This is the essence of the Physical Model: the properties of the spins in the sphere are the same as those of a paramagnet subjected to an external field, and it is possible to approximate them by a limited expansion in β , that is, limited to short-range correlations within the sphere, as described in *Low Spin Temperature NMR*. Afterwards, when considering the whole sample, the ‘Zeeman’ energy associated with this field is multiplied by $1/2$, to account for the fact that it is a self-energy, and the value of the field, a function of the nuclear polarization, is determined self-consistently. To the same order of approximation, this method yields results similar to the restricted trace method described above. The unique virtue of the Physical Model is elsewhere: unlike the other approximations, it can be used to describe the *dynamic* properties of the system.

The main motivation for developing this model was to account for the shape of the NMR absorption signal of ^{19}F in the transverse rotating helimagnetic structure. In this structure, the nonvanishing spin component expectation values are in the plane normal to the external field, in a helical arrangement. (More precisely, the nonvanishing Fourier components correspond to $\mathbf{k} \parallel \mathbf{B}_0$ and $ka \ll 1$, but are otherwise degenerate.) This structure looks static in the rotating frame. As viewed from the laboratory frame, the transverse spin components are rotating in bulk around $\mathbf{B}_0$ at the Larmor frequency—whence the name of this type of

ordering. It was observed that the (antisymmetric) absorption signal of ^{19}F consisted of two relatively narrow peaks flanked with bumps in the wings, whose importance depended strongly on the orientation of the field $\mathbf{B}_0$. The qualitative reason for this was soon realized. The condition $ka \ll 1$ makes it possible to isolate by thought in the sample a sphere of radius $R \gg a$ with practically homogeneously oriented transverse spin polarizations (which justifies the use of the Physical Model). The secular dipolar interactions, equation (2), are sums of components $\hat{T}_2^0(z)$ of spin tensorial operators, with respect to the direction Oz of the external field. In the sphere under consideration, it is natural to choose as the quantization axis the direction Ox of the spin polarization. With this choice, each tensor component $\hat{T}_2^0(z)$ is a sum of components $\hat{T}_2^0(x)$ and $\hat{T}_2^{\pm 2}(x)$. The latter mix states $|m_x\rangle$ with $|m_x \pm 2\rangle$. When an rf field is applied at frequency ω , it appears in the frame rotating at the Larmor frequency ω_0 as rotating at the frequency $\Delta = \omega_0 - \omega$. In the sphere under consideration, this rotating field can be decomposed into an oscillating component normal to Ox and an oscillating component parallel to Ox .

The former is able to induce transitions corresponding to $\Delta m_x = \pm 1$, and it accounts for the inner doublet. As for the longitudinal component, thanks to the state mixing described above, it is able to induce transitions corresponding to $\Delta m_x = \pm 2$, and it should account for the outer shoulders. Things are a little more complicated, because the transverse magnetization produced by the rf irradiation produces a transverse Weiss field on the other parts of the sample, which contributes to their own transverse response. The self-consistent calculation is rather complex. Performed within the Physical Model, it yielded a semiquantitative reasonable agreement with experiment.¹⁶

The validity of the Physical Model seems limited to structures where the mean field on a given spin originates from distant spins, and would seemingly exclude, say, antiferromagnetic structures. However, by analogy with the ‘vertex renormalization’ described briefly in *Low Spin Temperature NMR*, it might possibly be proved that it is also valid in such cases. This is so far but wishful thinking.

4 SPIN WAVES AND RPA

One of the simplest and clearest description of these approximations is found in Anderson’s ‘Concepts in Solids’.¹⁸

The spin wave approximation was initially developed by Felix Bloch for describing the low-temperature properties of ferromagnets. In the ground state, all spins are, say, in their eigenstate $\hat{I}_z^i = -I$. At low temperature, there will be few excitations, limited mostly to states where $\hat{I}_z^i = -I + 1$ would contribute. It is then a good approximation to treat $\hat{I}_+^i$ and $\hat{I}_-^i$ as boson creation and annihilation operators $\hat{\alpha}_i^+$ and $\hat{\alpha}_i^-$. One then finds that the excitations correspond to the Fourier transform operators $\hat{\alpha}^+(\mathbf{k})$ acting on the ground state, considered as ‘the vacuum’. The extension of this approximation to antiferromagnets has met with a little problem. For Heisenberg interactions of the form $J\hat{\mathbf{F}}_i \cdot \hat{\mathbf{F}}_j$, and also for secular dipolar interactions of the form of equation (2), an antiferromagnet where half the spins are in their eigenstates $\hat{I}_z^i = +I$ and the other half in their eigenstate $\hat{I}_z^j = -I$, corresponds to a state that is not an eigenstate of the Hamiltonian, because of the presence

of operators $\hat{I}_-^i \hat{I}_+^\mu$. This Hamiltonian has matrix elements between this trial ground state and excited states. As a result, the true ground state has an energy lower than the initial one. Formally, this true ground state is approximated in spin wave theory through a so-called Bogolyubov transformation on the initial pseudo creation and annihilation operators. This method has met with definite success at low temperature, much lower than T_c and out of reach of present studies of NMO. In NMO, we have made one successful qualitative use of spin wave theory, which can be described without any calculation. In CaF_2 , at positive temperature and with $\mathbf{B}_0$ oriented in the vicinity of the axis $[111]$, the L–T and Villain methods have two degenerate solutions for the ground state: a transverse helix described above, or a ferrosandwich with domains whose large dimension is parallel to $\mathbf{B}_0$, so as to minimize the energy—a requirement opposite to that at negative temperature. Discrimination between these possibilities can be obtained only by taking short range correlations into account. This is what is partly achieved by spin waves. The ferrosandwich is nearly an eigenstate of the Hamiltonian, except for the spins near the domain walls. The ground state energy is then close to that computed by the Weiss-field approximation. The existence of the domain walls is likely to increase it somewhat. As regards the transverse helix, it is definitely not an eigenstate of the Hamiltonian. As for the case of antiferromagnetism, the use of the spin wave approximation leads to the definition, through a Bogolyubov transformation, of a modified ground state, whose energy is lower than that of the initial state, i.e., that computed within the Weiss-field approximation. The qualitative result is that the (spin-wave amended) transverse helix has a ground state of energy lower than the ferrosandwich, and is therefore the stable ordered structure. The same conclusion has been reached at higher temperature through the restricted trace approximation, and it has been backed by experiment.

The random phase approximation (RPA), results in the definition of creation and annihilation operators of the same form as those in the spin wave approximation, with the difference that the energy of the excitations is ‘renormalized’: it is proportional to the ordered spin polarization. The theoretical approach may be similar to¹⁸ or very different from¹⁹ that of spin waves. Although expected to be an improvement over spin waves at not-too-low temperatures, RPA did not prove very useful for the study of NMO, except in one case that we describe qualitatively. It concerns the experimental evidence for the existence of transverse helimagnetism in CaF_2 . This evidence was provided by an experimental ‘paraphrase’ of the Hartmann–Hahn method: the resonant polarization transfer between two spin systems subjected to rf irradiation when their respective effective frequencies in the rotating frame are equal. The idea was that in the state of transverse helimagnetic ordering, the ^{19}F spins experience a transverse Weiss field, which should play the same role as the external rf field in the Hartmann–Hahn experiment. We have therefore subjected the ^{43}Ca spins to rf irradiation and studied as a function of effective frequency their rate of polarization through thermal mixing with the ^{19}F spins in the absence of irradiation of the latter. This rate exhibited a sharp maximum at a nonzero ^{43}Ca effective frequency, thereby proving that the ^{19}F spins experienced a Weiss field not aligned with the external field, i.e., at least partly transverse.

On second thoughts, the preceding interpretation is too simplistic. An elementary process of energy exchange between ^{19}F and ^{43}Ca proceeds through a flip of a single ^{43}Ca spin, but not through a flip of a single ^{19}F spin. The ordered system of fluorine spins can change its energy only through the creation or annihilation of elementary excitations, which involve many spins. We have used the RPA model for these excitations: their spectrum, density of states, probability of flipping a calcium spin. The predicted curve of polarization rate versus ^{43}Ca effective frequency is in qualitative agreement with experiment. More revealing, however, is that the variation of its shape when changing the external field orientation (that is the form of $\hat{\mathcal{H}}'_D$) is also as observed. In these experiments, the transverse fluorine polarization was about 0.7, as deduced from the Hartmann–Hahn-like resonance—a polarization high enough for RPA still to be a reasonable approximation.

We have not attempted other approximations such as Green functions beyond the RPA level, spherical model, etc. The accuracy of the experiments did not justify such an effort.

Abragam, Anatole: 'The Bible'

Anatole Abragam

Collège de France, Paris, France

Editor's Note: The following article, describing the writing of the classic work 'The Principles of Nuclear Magnetism', is taken from Professor Abragam's autobiography, 'Time Reversal', a charming, humorous and very informative book that was published in 1989. This excerpt is used with the permission of the author and the publisher, Oxford University Press.

I think it was in 1955 that Maurice Pryce told me that Oxford University Press (OUP) had asked him to write a book on magnetic resonance; but he did not have the time to do it, or did not feel like it, or both, and so he had mentioned my name to OUP and had been asked by them to sound me out for the job. 'It's just at the right moment', he said glibly. 'You have just completed a course on NMR and another on ESR: all you have to do is to translate it all into English and the trick is done'. I had no experience of the trade of book writing, I had only read a lot of them; but I understood that it would not be quite so simple.

What attracted and frightened me at the same time was that this book, which was yet to be written, would be part of the illustrious collection of the OUP Monographs. Before the war, it was with reverence that I used to contemplate their prestigious titles, written in letters of gold on the backs of their bottle-green bindings, standing on the shelves of the library of the Institut Henri Poincaré: *The Principles of Quantum Mechanics* by Dirac, the greatest physics book ever written, *The Theory of Atomic Collisions* by Mott and Massey, *The Quantum Theory of Radiation* by Heitler, *The Theory of Electric and Magnetic Susceptibilities* by Van Vleck, *The Principles of Statistical Mechanics* by Tolman—prestigious books, fountains of wisdom where I had quenched my thirst for knowledge. Could it be that my imperfect opus would stand next to them on the shelves?

I accepted timorously. A few weeks later I received two copies of a contract which, from the quality of the paper and of the typography, was more like a diplomatic treaty than a vulgar commercial agreement; OUP was already displaying the quality of its productions.

The contract was leonine: OUP reserved an exorbitant part of the television rights for itself, and declined all responsibility in case of prosecution for obscenity. Still, I accepted, asked Michel Trocheris to commit himself on my side by bearing witness to my signature, countersigned all the pages, and sent back one of the copies. *Alea jacta erat!*

Pryce had spoken lightly of some 300 pages to cover both ESR and NMR, while my lecture notes were already twice that size. I decided that I had to choose: ESR or NMR, that was the question. In 1955 I was far better known for my work on ESR than for my NMR; and I was advised by some friends to choose ESR where, I was told, I was an expert, rather than NMR where I was at best a beginner. I was not convinced: while I had hardly published anything on NMR, for five years I had read most of what was worth reading on the subject.

Furthermore I foresaw possibilities for development in nuclear magnetism, many more than I saw in ESR. Finally, in my infant laboratory, there were lots of things to be done straight away in NMR, and nothing of the kind in ESR. I made my decision. The book would be on nuclear magnetism and, in the wake of Dirac, I dared to call it *The Principles of Nuclear Magnetism*.

Then followed four years of strenuous work. One may well ask how, during these four years, I managed to combine the writing of a book of 600 pages (we were a long way from the projected 300 pages for NMR plus ESR), with the setting-up and the running of a new laboratory, and with my personal research. The answer is that there was a symbiosis between these various pursuits; my ideas and those of my young co-workers, and the results of our experiments, were fed into the book even while they were being submitted to scientific journals. Conversely, the writing of the book was at the origin of some of our researches.

For example, dissatisfied with the current theory of spin diffusion, I 'ordered' a better formulation from Pierre-Gilles de Gennes and entered it into the manuscript of my book even before he had published it in a journal.

I also liked to imagine experiments, aimed at illustrating some points of the theory in a spectacular manner. Some far from trivial experiments, which were performed in the lab during that period, originated purely for that reason.

I seldom presented a calculation taken from published literature without attempting to make it shorter, clearer, or more rigorous. I have already spoken of my efforts to strip Bloch's theory of the master equation of its Wagnerian mantle. I performed a similar operation of cosmetic surgery (I am mixing my metaphors) on a very important work, which was profoundly original but almost unintelligible, by Alfred Redfield. I heard from some of my readers that they understood Redfield's ideas for the first time in my presentation of them.

I kept strictly to my rule of including no theory in my book to which I did not subscribe, no experimental fact that contradicted a theory to which I did subscribe wholeheartedly, no formula that I had not checked myself. I departed from the last rule twice, to regret it both times.

All those who write books intended for students know, or at least ought to know, that they owe them a great responsibility, which is greater the better the students. A good student who reads a scientific book, pen in hand, trusts its author, and, when he comes up against an error, will waste a lot of his time trying to understand or to rederive the incorrect result. I am not saying that it is harmless to accumulate errors in an original scientific publication, but at least there the experienced reader will recognize earlier, and perhaps not without some innocent pleasure, the errors of a colleague.

This is why I took great care to detect any errors. I remember a formula cited by Bloembergen and Anderson (neither a Nobel laureate yet), with a discrepancy by a factor of four (or perhaps eight), while I myself had found a third result. Before including my own version in the book I had consulted with Walter Kohn and de Gennes, who fortunately both agreed with me.

In spite of all these efforts, small errors did remain, which readers pointed out to me and which I have, I hope, weeded out through the many printings the book has known during its long existence.

I found some relaxation from my labors by inventing short epigraphs which were appropriate to the contents of the various chapters. It is thus that I honored Marilyn Monroe (very much alive then) by giving the chapter on spin temperature the title of her picture: *Some Like it Hot*. OUP frowned at it; I replied, however, that to my knowledge it was the title of an old nursery rhyme, and what else did they have in mind?

In the preface I warned the reader (and the authors) that: ‘... in a book, in contrast to an article, no references need be given solely for credit ...’ By so doing, I considerably reduced the volume of the bibliography and made a few enemies.

The success of the book exceeded all my expectations and my hopes. It was translated into French (by André Landesman), Russian and Japanese, received a record number of citations for the last 25 years in the notorious *Citation Index*, and last but not least, sold very well.

If I have written at such length about the genesis of this book, it is not only because I lived cheek by jowl with it during the four years it took me to write it. It is also because it gets on my nerves, with the shadow it casts on the other things I have done.

Conan Doyle was deeply annoyed by the prejudicial effect of Sherlock Holmes’s success on some other works of his, which he considered at least as important. Well, I feel a little

like that too. All those who had anything to do with NMR, and that’s quite a crowd, know my name because of the book. Only a minority of them know that 10 years later Bleaney and I wrote an even thicker book on ESR, and still fewer know of my work after 1960 and of the book I published with Maurice Goldman in 1982, devoted to new developments in nuclear magnetism ‘with most of them coming from my own laboratory’. But, to tell the truth, I also sometimes think that the recognition I got for these other achievements is quite reasonable and in keeping with their value; it is the success of the *Principles* which may be excessive. Nobody is ever pleased with his lot.

Biographical Sketch

Anatole Abragam b 1914. Grad. Sorbonne 1938, D.Phil. Oxon, 1950. Introduced to ESR by Maurice Pryce and Brebis Bleaney, to NMR by Robert Pound, Ed Purcell and Felix Bloch. Professor of Nuclear Magnetism at the Collège de France (Paris) 1959-1985. Main fields of interest: hyperfine structure in solid state, perturbed angular correlations, dynamic nuclear polarization (DNP), nuclear magnetic ordering, nuclear pseudomagnetism, Muon precession. Publications in ESR, NMR, and other subjects. Books: ‘The Principles of Nuclear Magnetism’ (OUP 1961) and others.

Abraham, Raymond J.: A Brief History of Proton Chemical Shifts

Raymond J. Abraham

University of Liverpool, UK

The most important single parameter in high-resolution NMR spectroscopy is the proton chemical shift, and the classic demonstration by Arnold, Dharmatti, and Packard¹ of the three separate proton resonance peaks in ethanol illustrated the immense potential of NMR in structural organic chemistry. This was almost immediately recognized by Harold Bernstein and Bill Schneider at the National Research Council of Canada. They purchased one of the first commercial NMR spectrometers (a Varian 40 MHz spectrometer) and also invited John Pople to the NRC for a number of visits during the summers of the late 1950s. Thus, by an organizational tour-de-force, Harold and Bill had obtained both the facility for the production of a whole new set of experimental data and the cooperation of one of the finest theoreticians available to interpret it.

In 1957 I was working with Harold Bernstein as a postdoctoral fellow at the NRC, and was a student of and an admirer of both the first class science which resulted from this collaborative effort, including their seminal book on high-resolution NMR² (of which I suspect I have the only autographed copy in existence), and also of the excellent, informal, nonbureaucratic organization of the NRC at that time. This was indeed at times almost life-saving as they allowed me to sleep in their air-conditioned laboratory, which provided instant relief from occasional serious attacks of asthma precipitated by the high pollen count and humidity of Ottawa in the summer (at least compared to the UK!).

At this time, Allred and Rochow³ had shown conclusively how the proton chemical shifts of methyl derivatives (CH_3X) were linearly related to the electronegativity of X, and indeed used this relationship to define the electronegativities of some atoms and groups for which data were not available.

At the NRC, research into the fundamentals of proton chemical shifts proceeded in two separate directions. Spiess and Schneider⁴ made a comprehensive study of the proton chemical shifts of some simple gases, an exceptionally difficult experimental investigation given the comparatively poor sensitivity and stability of NMR spectrometers at that time. They attempted to eliminate the effects of the medium on proton chemical shifts, and their work showed the large effects that hydrogen bonding interactions have on proton chemical shifts, effects which even today have no quantitative theoretical explanation.

Another major project at the NRC was the determination of the proton chemical shifts of aromatic molecules, partially inspired by another basic concept in proton chemical shifts, the aromatic ring current. The simple equivalent dipole model of the benzene ring current proposed by Pople⁵ has been shown to be amazingly accurate. Despite subsequent more complex treatments,^{6,7} this simple equation⁸ is still the easiest method of accurately calculating the ring current field at any position

external to the benzene ring. The most spectacular illustration of the aromatic ring current is the proton spectra of condensed aromatic molecules such as the porphyrins and an extension of this dipole model, the double dipole or network model has been used successfully by our group to calculate proton chemical shifts both external to and within the porphyrin nucleus.⁹

The early research thus appeared at first to provide a complete understanding of proton chemical shifts. One could say in the early 1960s that proton chemical shifts were due to the charge on the proton, as illustrated by the effects of electronegative atoms on methyl proton shifts, modified by the shielding effects of anisotropic groups, such as aromatic compounds, carbonyl groups, etc., and by medium/complexation effects (in particular, hydrogen bonding, both intra- and intermolecular). It looked as if everything was falling in place.

Unfortunately, as so often happens in science, the truth was rather more complex and less comprehensible than our simple explanations had implied. The linear relation of CH_3X proton chemical shifts with the electronegativity of X would imply that the partial atomic charge on the proton determines proton chemical shifts. This, however, was not confirmed by quantum mechanical calculations. Indeed, modern sophisticated *ab initio* calculations using the Mulliken population analysis predict that the positive charge on the protons of methyl fluoride is *less* than on the protons of methane. On the simple basis of charge versus proton chemical shift, the methyl fluoride chemical shift should be upfield of that of methane!

Furthermore, it was noticed that although the chemical shift difference $\delta(\text{CH}_3) - \delta(\text{CH}_2)$ of the protons in ethyl derivatives also correlated linearly with the electronegativity of the substituent, the actual shielding of the CH_3 protons *increased* with increasing substituent electronegativity, i.e., opposite to expectations.

Even worse, solvent effects on proton chemical shifts were found to be large¹⁰ and could not be ignored in any quantitative calculation of proton chemical shifts even where hydrogen bonding was not involved.

And finally, even in simple hydrocarbons with no anisotropic or polar groups, large differences in proton chemical shifts were observed. The classic example was cyclohexane in which the axial and equatorial protons resonate at δ 1.19 and 1.68 ppm. This last result proved the final straw. The only acceptable explanation of this difference was that it was due to C–C bond anisotropy, but the major difficulty with this explanation was that the anisotropy had to be so large to obtain the experimental shift difference that the C–C bond would have to be paramagnetic in one direction!

So what happened then? NMR spectroscopists discovered FT NMR, noise decoupling, ¹³C NMR, and subsequently a whole new world of multidimensional NMR. The interpretation of proton chemical shifts was left to undergraduate classes, and they fortunately do not usually ask any questions!

However, some researchers continued this by now unfashionable research topic. Steric effects were shown to be important in proton chemical shifts,¹¹ and advances in molecular modeling and our knowledge of molecular geometries meant that these could, for the first time, be calculated at least semi-quantitatively.

The effect of a vicinal methyl group on the proton chemical shift was shown to be a function of the C–C–C–H dihedral angle.¹² In a *gauche* orientation the methyl is shielding,

whereas in a *trans* orientation the methyl is deshielding, with a ca. $\cos \phi$ dependence.

Also, in contrast to quantum mechanical calculations, semiempirical calculations of partial atomic charges gave remarkably good correlations with proton chemical shifts.^{13,14}

Does this mean that proton chemical shifts are a function of the partial atomic charge on the proton after all?

We have recently reinvestigated this question, and produced a simple scheme for calculating proton chemical shifts based on a semiempirical calculation of partial atomic charges together with an orientational dependence of electronegative substituents and including also steric effects.¹⁵ To date this scheme has been applied successfully to hydrocarbons and simple acyclic molecules. On this scheme the axial versus equatorial chemical shift difference in cyclohexane is simply due to the orientational dependence of the vicinal carbon atom, the equatorial proton having two vicinal carbon atoms in an *anti* (*trans*) orientation, whereas the axial proton has the carbon atoms in a *gauche* orientation. Is this the true explanation, or will proton chemical shifts continue to baffle the theoretical chemist? As usual, only time will tell.

Ackerman, Joseph J. H.: Oxford Knights

Joseph J. H. Ackerman

Washington University, St. Louis, MO, USA

In the mid-1970s I was a physical chemistry graduate student in Gary Maciel's group in the Department of Chemistry at Colorado State University. My research life had been consumed with liquid and solid state multinuclear MR experiments particularly those involving metal nuclides. David Hoult came by to give a seminar. He talked about the marvelous high sensitivity ^{31}P NMR spectrometer he and his University of Oxford colleagues had put together under the aegis of the Rex Richards/George Radda research group. David showed beautiful new results demonstrating detection of the major phosphorus metabolites in intact isolated muscle tissue.

A few years later I found myself an NIH postdoctoral fellow in the same University of Oxford laboratory. Space was limited. I shared a desk along with Tom Grove, a NATO postdoctoral fellow, and Gordon Wong, a Rhodes Scholar. David Gadian, a bright young physicist, was now taking over the science reins from Rex Richards. Despite his time-consuming high level administrative duties as Warden of Merton and Vice Chancellor, Rex still dropped into the laboratory now and then to talk science and be brought up to date on recent developments. David Hoult had left for the NIH in Bethesda and spectrometer building and design were now in the very capable hands of Peter Styles, Rod Porteous and Nick Soffe.

A principal focus of the laboratory was on perfused organ ^{31}P NMR experiments with the Radda group exploring rat heart physiology and Gadian and co-workers pursuing frog skeletal muscle metabolism. Efforts focused on carefully excising the tissue or organ of interest and interfacing the sample to a perfusion support system. True to everyone's training in the dogma of high-resolution NMR, and as had been done for decades before, the sample was placed *inside* the NMR antenna coil. Prior to placing the tissue in the magnet the static field homogeneity was optimized by shimming on a test sample containing a concentrated phosphorus solution so as to give a strong ^{31}P free induction decay.

My first contribution was to introduce a technique taught to me by my close friend and mentor Jerry Dallas who had also been a graduate student in the Maciel group pursuing multinuclear MR. This was that one can often shim on the solvent ^1H free induction decay even if the antenna coil is frequency tuned and impedance matched for a nuclide at a different resonance frequency, say that of ^{31}P . Although this idea met with some disbelief at first among my Oxford co-workers, the ^1H tissue water signal was found to be very strong from the ^{31}P antenna coils used for perfused rat heart and other organs. One could now routinely shim directly on the tissue sample of interest.¹ The ^{31}P linewidth resolution improved significantly. For example, the intracellular and extracellular inorganic phosphate signals in perfused rat heart were now readily resolved. The respective pH values were determined from their chemical shifts.

Tom Grove and I became good friends. We also were pursuing perfused rat heart experiments.² Tom decided to

explore the possibility of studying the tissue *in situ* by implanting the antenna coil about the heart with the entire rat, fully anesthetized and breathing on a respirator, then going into the magnet. This approach required rather radical surgery and taught me a great deal about antenna loading by lossy conductive samples. Nevertheless, the experiments worked well and were, I believe, perhaps the first localized *in situ* and *in vivo* ^{31}P measurements.³

Flush with this success, we joined with Gordon Wong—a budding molecular biologist trapped for a short while in an NMR laboratory—to repeat this approach with rat kidney. Gordon, under the guidance of David Gadian and Brian Ross, had been struggling mightily with a difficult perfused kidney preparation.⁴ Tom and I thought the implanted coil offered perhaps a better idea.

It was not to be. Try as we might, the *in vivo* ^{31}P kidney spectra showed substantial levels of phosphocreatine, a compound essentially absent in renal tissue but not in the surrounding muscle tissue. Clearly the antenna coil so carefully designed to surround the kidney was exciting and detecting signals from outside the coil.

I remember well the repeated unsuccessful attempts to pack gauze pads about the coil in an attempt to push the surrounding tissue out of the antenna coil's transmission/reception range. It was 2 a.m., the jokes were getting stale and tempers a bit edgy, when I realized the all-too-simple lesson in front of us: samples don't have to be inside the antenna coil to be detected. I walked out of the spectrometer room and down the hall to our office. This cramped space also served as the coil-design electronics laboratory. The first surface coil was wound. A simple tank circuit frequency-tuned and impedance-matched the surface coil to ^{31}P —80 MHz at 4.2 T.

I returned to the spectrometer room to find even more gauze packed about the implanted kidney coil. Tom and Gordon were clearly fed up with the kidney experiment. They agreed to humor me. We put the surface coil on the rat thigh, the largest muscle group. One of us ventured that if we could just get enough ^1H tissue water signal to shim the field we might have a chance with the ^{31}P experiment. We were stunned, the ^1H FID was enormous. Shimming was remarkably easy. Tom, Gordon, and I quickly switched the spectrometer over to ^{31}P . Within minutes a beautiful muscle spectrum showing inorganic phosphate, phosphocreatine, and the α -, β -, and γ -phosphate resonances of ATP was in hand.

It seemed almost too easy. How quickly one forgets the years of training leading up to a 'simple' finding. We had all been used to continually struggling with complex and delicate organ perfusion systems. All of our NMR training had taken as a given that the sample was placed inside the antenna coil. Now, in one early morning experiment all that changed.

The next few weeks were a frenzy of activity. David Gadian worked out the antenna theory to explain just why surface coils were so sensitive and what their localization properties were. Tom, Gordon, and I repeated the muscle experiments and extended this approach to rat brain ^{31}P analysis. George convinced us that the name surface coil was better than any of the names I came up with. A manuscript was submitted to *Nature*.⁵

A few months later I left for Washington University in St. Louis. Two a.m. seems awfully early to me now.

Ailion, David C.: The First Observations of Ultraslow Motions

David C. Ailion

University of Utah, Salt Lake City, UT, USA

I was a graduate student in the Physics Department at the University of Illinois in the late 1950s and early 1960s. Initially I thought that I wanted to be a theorist, but after having done some calculations for Jim Koehler for a year or so, I realized that I knew absolutely nothing about experimental methods. Since I didn't want to have such a gap in my education, I decided to try to work for a group that used a variety of different experimental techniques. Charlie Slichter's NMR group appeared to be such a group, and it also had a fine reputation for doing important physics.

In those days Charlie used the apprentice system—a new graduate student would work under a late-stage student and, in exchange for providing assistance, would 'learn the ropes'. My initial assignment was to assist Bill Simmons, who was interested in looking at metallic indium. Because of the skin depth it was important to obtain a powder sample, which was usually obtained by filing a chunk of the material manually and then passing the filings through a sieve to obtain small particles. As luck would have it, indium is very soft at room temperature, so filing it would be like filing butter. I constructed a holder which rigidly clamped one end of an indium bar and submerged the other end in liquid nitrogen. My 'baptism under fire' (as Charlie called it) consisted of spending several weeks filing this bar in liquid nitrogen. I never found out what happened subsequently to the powder or to the experiments planned with it.

There was a coffee pot in one of the labs, and Charlie would generally show up between 8.00 a.m. and 8.30 a.m. to get a cup of 'red-eye', as he called it. At that time he would be happy to talk with any of his students about their data from the night before. (Yes, we were expected to work at night!) Since Charlie was very busy, often this was the only opportunity that we would have to speak to him. It was also an extremely effective way for Charlie to get his students into the lab early.

Charlie hated to throw away anything that might be potentially useful; as a result, his labs were cluttered with equipment constructed by former students. Unfortunately, much of this equipment had already seen its best days and no longer worked. Charlie felt that a good way for a student to get started in electronics was to repair or otherwise make operational some of this older equipment, even though circuit diagrams often did not exist. He also believed that the best way for a student to master NMR equipment was to build it. This was a convenient philosophy since very little NMR equipment was commercially available then. Since it appeared likely that my thesis research would involve the measurement of relaxation times, Charlie asked me to construct a 'boxcar' circuit like that constructed years earlier by Holcomb and Norberg. Their circuit utilized vacuum tubes, as did most of the NMR equipment at that time, since transistors were beginning to be used more widely only towards the end of my graduate

student days. After much wasted time, I finally persuaded Charlie to allow me to build a different kind of boxcar, one designed by R. J. Blume, which used expensive (\$20 each!) ceramic diodes with a very favorable ratio of forward to back resistance. This circuit worked like a charm, and my construction of it did more to build up my self-confidence than anything I had done until then.

One of the fringe benefits of working in Slichter's lab at Illinois was that we would get visits from very famous scientists. Erwin Hahn would often grace us with his valuable insights and his funny jokes. Another frequent visitor was Al Redfield, who had in 1955 developed the concept of spin temperature in the rotating frame.¹ This idea was that a spin system subject to a very strong rf field B_1 would form a canonical distribution among the Zeeman levels in the rotating frame of B_1 . In 1961 Charlie persuaded Bill Holton, who had just finished his Ph.D. thesis and was awaiting his exam, to attempt an experimental verification of Redfield's hypothesis by performing an adiabatic demagnetization experiment in the rotating frame.² This experiment consisted of transferring lab-frame Zeeman order to rotating-frame Zeeman order by simply slowly sweeping the static field B_0 from way off-resonance to on-resonance. For several nights Charlie and Bill worked until the wee hours of the morning. The experiment was successful, and they had thereby demonstrated the possibility of performing a truly significant experiment in a very short time, if one has a sufficiently good idea. This experiment paved the way for my later work on ultraslow motions.

It was, of course, well known that atomic diffusion could result in a minimum in a plot of the temperature dependence of T_1 . This minimum would occur when the atomic jump rate $1/\tau$ equals the Larmor frequency ω_0 ($= \gamma B_0$). Thus, if one could perform an experiment in a sufficiently small magnetic field, the T_1 minimum would come from much slower motions (a longer value of τ). The problem was how to perform an NMR experiment in a very small magnetic field without losing all the signal. In the mid-1950s Charlie and another illustrious student, Chuck Hebel, had measured T_1 in zero magnetic field in superconducting aluminum³ by performing a laboratory frame demagnetization followed after a variable time by a remagnetization. By plotting the signal following the remagnetization as a function of time in the demagnetized state, T_1 in zero magnetic field could be measured. To perform such an experiment to detect very slow diffusion would require a demagnetization of several thousand gauss, which in turn would require several seconds to be adiabatic. During this time the normal T_1 processes would in most cases relax the magnetization, thereby preventing the observation of the slow motions. As a result of his familiarity with Redfield's hypothesis and his experiment with Holton, Charlie got the brilliant idea that this difficulty could be overcome by performing an adiabatic demagnetization in the rotating frame. The role of B_0 in determining the T_1 minimum would then be played by B_1 , in which case the minimum would occur when $\omega_1 \tau = 1$, where $\omega_1 = \gamma B_1$. Since B_1 could be of the order of a few gauss instead of several thousand gauss, such an experiment could result in the detection of motions three orders of magnitude slower than those detectable by ordinary T_1 measurements. He suggested to me that the experimental verification of this idea by measuring the rotating-frame relaxation time $T_{1\rho}$ for a diffusing system would be a suitable topic for my Ph.D. research.

I then had two problems. One was to get the equipment to the point where I could perform the experiment, and the other was to understand the underlying physics. It was clear that even slower diffusion could be observed by performing a second adiabatic demagnetization in which B_1 is reduced to zero. One question was where would one expect the T_1 minimum to be in zero magnetic field. It was clear that at ω_0 or ω_1 equals zero the T_1 minimum couldn't be at $\tau = \infty$, since the Bloembergen, Purcell, and Pound (BPP) theory would not be valid in zero magnetic field. The BPP theory, which predicts that the minimum should occur when $\omega_0\tau = 1$, is a perturbation theory that assumes that the fluctuating dipolar Hamiltonian can be treated as a perturbation on the Zeeman levels. Such a theory would clearly break down at zero field since then there would be no Zeeman Hamiltonian. Accordingly, assuming that one could measure the relaxation due to diffusion in a very weak (or zero) magnetic field, a very different kind of theory would be required to relate τ to the measured relaxation time. After discussing this point with Peter Mansfield, who was at that time a postdoc attempting to do double resonance, I realized that, in zero field, the relaxation time minimum would occur when $\tau \approx T_2$. The second adiabatic demagnetization would transfer rotating-frame Zeeman order to dipolar order. Since there would then be a canonical distribution among the dipolar levels, with a splitting proportional to ω_d , the minimum of the zero-field T_1 (subsequently called the dipolar relaxation time T_{1d}) should occur when $\omega_d\tau = 1$ or $\tau \approx T_2$, which would be at the onset of motional narrowing. Only T_1 would limit the value of τ that could be detected. Since T_1 could be seconds to hours in length, motions could in principle be observed that were far slower than any that had been detected previously by NMR. We solved the theoretical problem of determining the jump time τ from the measured $T_{1\rho}$ or T_{1d} by developing a spin temperature theory⁴ (the so-called *strong collision* theory) to replace the BPP perturbation theory. This theory is valid only in the 'rigid lattice' (where $\tau > T_2$), and thus complements the region of validity of BPP.

There was also work that I had to do to get the equipment ready to do the experiment. Most of the T_1 measurements performed prior to this work utilized short hard pulses. Since $T_{1\rho}$ or T_{1d} could be seconds or longer in length, it was necessary to modify the power amplifier so that it could generate very long pulses. (This turns out to be not always necessary for T_{1d} measurements, however.) In addition, a highly stable magnetic field was desirable to ensure that the magnetic field was exactly on resonance. The magnet available in the lab was a hand-made 12 in. electromagnet that had current regulation but no field stabilization. The field stabilization method that I developed was very primitive and consisted of a feedback loop of which the experimenter was part. I constructed a CW NMR spectrometer, a marginal oscillator containing a narrow-line sample (water), to monitor the field. A frequency counter was used to monitor and eliminate frequency drifts in the marginal oscillator. Prior to each measurement of $T_{1\rho}$, I readjusted the drifted magnetic field to its original value, so that all the measurements occurred at the same magnetic field.

The sample which we decided to look at for our initial experiment was metallic lithium powder. Holcomb and Norberg (HN) had performed T_1 and T_2 measurements in the alkali metals⁵ and had shown that the onset of motional

narrowing in lithium occurred at a convenient temperature (just below room temperature). Because of the skin depth, it was important to obtain a powder sample and, because of the reactivity of lithium with water, the sample was immersed in mineral oil.

On 12 June 1963, I performed the first $T_{1\rho}$ measurement on lithium powder and observed, much to my delight, that its value was orders of magnitude shorter than T_1 at the same temperature, suggesting that our ideas were correct and that we indeed should be able to study ultraslow motions by this technique. After taking the first data point, I had to leave the lab since it was my fiancée's birthday, and I had promised to take her out for dinner. However, later that night I sneaked back into the lab to take another data point, to make sure that my success was not a dream. It wasn't, and it was with great pleasure that I presented my results to Charlie over coffee the following morning.

Over the next several months we established this new method for studying ultraslow atomic motions. In particular, we confirmed the validity of the strong collision theory by showing that the values for τ obtained by applying the strong collision theory to our $T_{1\rho}$ results in the rigid lattice region agreed very well with an extrapolation of HN's values for τ obtained by applying BPP to their T_1 data.⁶ (For a more complete discussion of the theoretical and experimental features of the ultraslow motion techniques, see *Ultraslow Motions in Solids* in this Encyclopedia.)

Aime, Silvio: A Taste of NMR in Inorganic Chemistry

Silvio Aime

Università degli Studi di Torino, Torino, Italy

It was by sheer chance that I encountered NMR. In the late 1960s organometallic chemistry was experiencing a particularly good period of development with the discovery of a number of interesting reactions. Among them, the oxidative addition of unsaturated substrates to transition metal carbonyl clusters was especially attractive for the senior research fellows in the Inorganic Chemistry group at the University of Torino. These reactions often promote the formation of hydrides, both terminal and bridging two or three metallic centers. None of the available techniques (IR, MS, X-ray diffraction) provided firm support for the occurrence of the metal–hydrogen bond. NMR spectroscopy did! Although the reason was not well understood at that time (and probably now as well) the hydride resonance was observed in a characteristic high-field region, about 10–20 ppm upfield from TMS. Since then NMR has become for us the technique of excellence for assessing the formation of hydride products in our organometallic reactions. Its powerful capability for elucidating the exotic structures of organometallic cluster derivatives quickly attracted everyone's interest to the new NMR technique.

Later, in the early 1970s, when we obtained an FT spectrometer we gratefully appreciated how unique NMR is for the investigation of stereochemical nonrigidity in metal carbonyls. It was very exciting to discover how many different exchange processes of carbonyl ligands were possible over the surface of metal clusters and how the exchange processes of different ligands could be concerted.

Organometallic chemistry owes much to NMR spectroscopy. Both the number of active nuclei usually present in organometallic compounds (metals, ^1H , ^{13}C , ^{15}N , ^{31}P . . .) and the variety of exotic bonding schemes make organometallic molecules particularly suitable for NMR investigation.

Later our interest focused on the relaxation properties of organometallic compounds and we found that several structural and dynamic problems may be tackled by measuring longitudinal and transverse relaxation times, often as a function of temperature and magnetic field strength. For example, the position of hydride ligands bonded to heavy transition metals, a problem that normally requires neutron diffraction data, may be determined directly in solution from an analysis of the dipolar contribution to the longitudinal relaxation time.

Furthermore, in the presence of chemical exchange we showed that the thermodynamic parameters of the exchange processes may be calculated by comparing T_1 and T_2 values for hydride ligands at different temperatures.

An improvement relevant to our studies of organometallic chemistry was achieved, more recently, by the availability in our laboratory of solid state NMR equipment. Particularly interesting applications, both with wide-line and high-resolution techniques, were carried out in the VT investigations of the dynamic behavior of organometallic compounds containing cyclopentadienyls, arenes, and hydrides.

In 1986, when I moved from the Faculty of Science to the Faculty of Pharmacy, I was looking for some new research fields capable of linking inorganic chemistry with biomedicine and NMR spectroscopy in order to accomplish my new duties better and to attract more interest from new students. This led me to investigate the physicochemical properties of paramagnetic lanthanide complexes in view of their use as contrast agents for magnetic resonance imaging. On entering the fascinating world of paramagnetic systems, where the spectroscopic answer is so nicely amplified, someone used to the scale of diamagnetic species is initially shocked! Lanthanide(III) complexes may afford proton spectra covering hundreds of ppm, allowing then the discrimination of very minor structural differences in the surroundings of a given resonance. A relevant role in these studies was the discovery of the huge potential of relaxometry in describing the structural and electronic properties of Gd(III) complexes.

We are lucky enough to have in Italy (at the University of Florence) a fully automated field cycling spectrometer developed by S. H. Koenig and R. D. Brown, III (IBM, NY) that provides the best way to accomplish such studies.

I would like to conclude by saying that although nothing is very special in this 20-year story, the personal pathway sketched in this brief report may closely resemble the story of many (hundreds, thousands?) of researchers who had the fortune to meet the splendid armory of NMR spectroscopy early in their career.

Currently Professor of General and Inorganic Chemistry at the Faculty of Pharmacy of the University of Torino, Italy. Approx. 160 publications. Research specialties: solution structures and dynamics of coordination and organometallic compounds, solid state NMR, relaxometry of paramagnetic complexes.

Anderson, Weston A.: Early NMR Experiences and Experiments

Weston A. Anderson

Varian Associates, Palo Alto, CA, USA

EARLY SCIENTIFIC INTERESTS OF THE AUTHOR

I have been told that at a very early age, before I learned to walk, I showed interest in lights and plugs. It somehow must have been born in me, but not directly inherited, as my father was a banker and my mother a nurse. As I grew into my boyhood I collected batteries, lights, motors, buzzers, and the like, and was fond of hooking them together. In my early teens an uncle taught me a lot about radio. During my high school years I experimented with radio and got both a commercial radio license and a radio ham license (W6API) which I have kept up to this day. In high school I took physics and chemistry which I greatly enjoyed. My teacher in these two subjects, Mr. Gilbert Ewan, was a graduate of Stanford University, and he encouraged me to go there. I lived at home for my first two years of college, attending Reedley Junior College (now Reedley College).

ON TO STANFORD

In 1948 I transferred to Stanford as a junior. I majored in physics with minors in electrical engineering and math, receiving a B.S. degree in 1950. I continued on at Stanford for a master's degree and finally a Ph.D. For my thesis I worked on nuclear magnetic resonance (NMR) under Professor Felix Bloch, who in 1952 shared the Nobel Prize with Edward Purcell of Harvard for their discoveries. The work that Bloch did for the prize was done before I came to Stanford.

Those were exciting times. When I started my thesis work, Jim Arnold was already in the process of building a permanent magnet for a new NMR spectrometer that (hopefully) would have very high magnetic field uniformity and time stability. This would enable him (and me) to study very small shifts and splitting that he and others had recently detected in various chemical compounds.¹ Using my earlier experience with radio, I built the rf transmitter and receiver for the experiments. When the magnet and electronics were finished, we found the magnetic field dropped off faster than anticipated. To compensate for this drop-off, Jim built a set of current shims that consisted of a spiral pancake of wire on each pole face, with many taps so the current in each section could be independently regulated. The linear transverse gradients were controlled by slightly changing the tilt of the pole pieces by adjusting a set of differential screws. It was often a tedious job to adjust the field homogeneity, because the controls were not independent. In addition, small temperature changes in the room caused the magnetic field to drift, so we became very

adept at raising and lowering the windows and turning a small heater on and off.

Professor Bloch suggested² that if we could completely stir the sample rapidly within the sample tube, the effect of the magnetic field variations over the sample volume could be essentially eliminated. After many unsuccessful attempts to achieve complete mixing, we settled upon spinning the sample, which caused averaging over concentric circles centered on the axis of rotation. This partial averaging was a great improvement as it made the job of magnet shimming much easier.³

My thesis work dealt with taking the NMR spectra of various chemical compounds, and then analyzing spectra to derive the chemical shifts and spin coupling constants. Quantum mechanics was used to do the analysis, which I found fascinating. The title of my Ph.D. thesis was 'Nuclear Magnetic Resonance Spectra of Some Hydrocarbons'. Several years later, after publishing a paper with the same title,⁴ a chemist friend told me that the molecules that I studied and analyzed were not hydrocarbons!

In the summer of 1954, Professor Bloch received an offer to become Director General of the newly formed European Centre for Nuclear Research (CERN). It was then temporarily headquartered in Switzerland at the University of Geneva. Bloch asked me to write my thesis on the work I had been doing. Because of the time pressure, I wrote it and had it accepted in approximately two weeks.

WORKING AT CERN

Professor Bloch thought it would be good to get some research work started at CERN. Up to that time the main activity had been planning and developing the site. He proposed that Jim Arnold and I go with him to CERN, take along some of our equipment, and do some experiments. We happily agreed.

We spent an interesting year in Geneva. We did some work,⁵ too, but not a lot, and did some skiing on the weekends. That was a very pleasurable year, and I met some other fascinating physicists. Professor Anatole Abragam, who was at Saclay at that time, came periodically to visit CERN. We went out to concerts and other places with him. There's a story he reported in his book, *Time Reversal, An Autobiography*, that I've told often, and now he's told it on himself.

There was to be a meeting of the Faraday Society⁶ in Cambridge, England, and Jim and I decided to report about our work at Stanford. I was going to give the talk, and Abragam told me, 'These are only 10-min talks, but if you have someone in the audience ask questions, then you have some extra time while answering the questions'. So we went through all of my material and picked out a slide that needed more elaboration, and he agreed to ask a question about it. In due time, we went off to the meeting and I gave my talk, after which he asked the agreed-upon question. Then the embarrassing moment came. In response to his question, I said, 'I'm sorry, I didn't have time to show that slide'. I don't know if he's ever forgiven me for that. He said later that he knew the material so well that he wasn't listening to what I said.

Originally, Bloch had planned to stay at CERN for two years, so Jim and I would have been there two years also, but after one year, Bloch had had enough of it. It was

more administration than he liked. He decided to go back to Stanford. Then I had to decide just what I wanted to do. In 1951, I had worked at Westinghouse Research Center in Pittsburgh during the summer quarter. In the summer of 1952, I worked at Varian Associates in San Carlos, at the original site where the company started. I had job offers from both companies, as well as an offer from Anatole Abragam to work at the French Atomic Energy Commission at Saclay. I was pleased that Professor Abragam had apparently forgiven me, and I think I would have gone to Saclay except the draft board contacted me and suggested that I come back to the States. Being a native Californian with the hope of keeping my roots in California and the chance to continue work in magnetic resonance led me to choose Varian.

VARIAN ASSOCIATES AND THE BLOCH–HANSEN PATENT

Before continuing with my story, let me step back and give some background of how Varian was founded and got into NMR. I give here only a bare outline; a rather complete version of the story can be found in the book *The Inventor and the Pilot* by Dorothy Varian.⁷ Russell Varian (called Russ by his friends) is perhaps best known for his invention of the klystron tube, however he also made many important contributions to the field of NMR. His acquaintance with NMR started in mid-1946 when he returned to Stanford from Sperry on Long Island, New York, where he and several Stanford people had worked to perfect the klystron and incorporate it into the early radar systems. The discovery of NMR had taken place less than a year earlier at Stanford under Felix Bloch,⁸ and at Harvard under Edward Purcell.⁹ Russ immediately conceived the idea that NMR could have important applications as a method of chemical analysis. The only published NMR signal at that time was that of water, which is reproduced in Figure 1. On the basis of this spectrum and others like it, and from what was known about NMR at that time, it seems remarkable that Russ Varian believed it could become a useful tool for chemical analysis. At this time the chemical shift and the spin–spin couplings between nuclei were yet to be discovered. Russ told Felix Bloch and Bill Hansen about his ideas of chemical analysis and urged them to apply for a patent. Bloch felt the technique would be of interest only to a few academic physicists who might want to measure magnetic fields or magnetic properties of nuclei. Since Bloch showed little interest in applying for a patent, Russ offered to prepare a patent application and handle its filing in return for an exclusive license for himself and his brother, Sigurd, with the understanding that the license could be transferred to his company when it was established. They agreed, and Russ wrote a good part of the patent application with help from Bloch, Hansen, and his patent attorney, Paul Hunter. Russ incorporated the idea of chemical analysis in the claims and titled the patent *Method and Means for Chemical Analysis by Nuclear Induction*. The patent was filed in December 1946 and was issued in July 1951.¹⁰

Tellegen, who was at Philips Research Laboratory in Eindhoven, Holland, developed the mathematical concept of the gyrator. He described it as a new electric network element that violated the reciprocity relation but was consistent with the laws of physics. He published this work in 1948 and 1949.¹¹

Figure 1 First NMR signals, reported by Bloch, Hansen, and Packard. (From Ref. 8c)

Les Hogan, who was at Bell Labs, developed a practical gyrator using ferromagnetic materials, which depends upon the gyromagnetic properties of electrons. He applied for a patent in 1950, which was issued in 1951 and immediately put under security orders. When the order was lifted, Hogan immediately published his material in the *Bell Labs Technical Journal*.¹² In this paper, Hogan pointed out that the nuclear resonance phenomena observed by Bloch also satisfied the gyrator relationship.

Marvin Chodorow, a professor at Stanford, received a copy of the *Bell Labs Technical Journal* and realized that since the phenomena described by Hogan and Bloch were the same, there was a deficiency in the Bloch–Hansen patent application. By this time, the original Bloch–Hansen patent had been issued, so it was necessary to file for a reissued patent. The wording of the original patent was changed to include resonance of electrons as well as nuclei by inserting the words ‘portions of atoms’, where previously the words ‘nuclei of atoms’ had been used. New claims were also added that broadly covered the gyrator concept. The Bloch–Hansen patent was finally reissued in 1955.¹³

Varian Associates was incorporated in the state of California in April 1948. The name ‘Varian’ was used because it was the well-known name of the inventor of the klystron tube, and ‘Associates’ because the founders wanted to convey the idea that this was going to be an association of equals. The purpose of the company, as stated in the charter, was to conduct research in the fields of physical science of every kind or nature, including heat, sound, light, X-rays, charged particles, ionizing radiation, properties of solids, liquids and gases, chemistry, and to measure the gyromagnetic ratio of nuclei of atoms, and to use the gyromagnetic properties of atoms to measure magnetic fields or for other purposes. The Articles of Incorporation described a number of fields in which the company became a leader including NMR, linear accelerators, optical spectrometers, and microwave tubes.

RUSS VARIAN AND HIS MAGNETOMETER

After I arrived at Varian Associates in September 1955, I became involved with magnetometers. This got me deferred

from military service because the magnetometers had military applications, which included searching for land mines and hunting submarines. I worked on what is called a 'free precession magnetometer' that Russ Varian had invented.¹⁴ Russ had conceived the idea in 1948, less than three years after NMR had been discovered. The idea of free precession formed an important part of what later became Fourier transform (FT) NMR. The concept of his magnetometer is quite simple. Protons in a bottle of water are polarized by sending a strong electrical current through a coil that surrounds the bottle, producing a strong magnetic field in the water sample. The coil is oriented so the strong magnetic field is approximately perpendicular to the Earth's magnetic field. After a few seconds the protons in the water become polarized, and a majority point in a direction of the strong magnetic field, i.e. along the axis of the coil, which is perpendicular to the Earth's magnetic field. Then the polarizing field is quickly turned off, and the protons are left in this position. They immediately start to precess about the Earth's magnetic field, and in doing so they induce a current in the coil which has a frequency that is proportional to the strength of the Earth's magnetic field. The coil is quickly switched to the input of a sensitive amplifier and a frequency meter. The measure of that frequency gives a very precise value for the Earth's magnetic field.

It's a simple device, but you have to be careful about several things. One of these is the current turn-off circuit. If you turn off the polarizing magnetic field too slowly, the proton nuclei will follow the changes in direction of the magnetic field, slowly swinging back until they point parallel to the Earth's field, and then they won't precess. If you turn off the current too rapidly, before dissipating the energy stored in the coil, a transient oscillatory magnetic field is produced and the protons become disoriented and do not remain perpendicular to the Earth's field. I developed a circuit that would turn off the field quickly and remove the energy that is stored in the coil without disrupting the orientation of the protons. I was also involved in developing coil configurations that would reduce or eliminate external interference arising from low frequency electromagnetic fields.¹⁵

In order to test the magnetometer at various values of the external field I built a set of coils to simulate the field changes that might occur naturally or occur in other parts of the world. The set, shown in Figure 2, consisted of four coils arranged so that the first uncorrected gradient was of 8th order.

A portable free precession magnetometer was developed and sold commercially. One application that generated a lot of publicity, but not much profit, was using the magnetometer to locate skiers buried in an avalanche. The skier would wear a small magnet obtained at the ski lift. Should the skier happen to be trapped by an avalanche, a search team with the magnetometer could quickly locate the magnet under many feet of snow and dig the person out.

Russ was a very clever guy and one of the things that I really enjoyed about the early years at Varian was the interaction with him. He would come around and talk; and he talked to everyone, not just me. That's one of the things that's changed from the early days at Varian. There are lots of stories about Russ. One I remember is about the time Russ had a visitor from India. Russ was bringing the visitor through the front door, and Pete, the janitor, was sweeping up there. Pete said, 'Hello, Russ'. And Russ said, 'Good morning, Pete', as they

Figure 2 Young Anderson with magnetic field biasing coils used to change the magnetic field at the bottle of water sensor of a free precession magnetometer

Figure 3 Photograph of Russell Varian taken in the mid-1950s

walked by. The Indian visitor was astonished that the janitor would address the president of the company by his first name.

Russ was absent-minded, and another story about him was from the early days in San Carlos. He had recently moved into a new house. One day, forgetting that he had moved, he walked into his old house and surprised the people who were living there.

HIGH-RESOLUTION NMR EXPERIMENTS

Soon after starting my full time job at Varian, I also became involved in improving the performance of the NMR

spectrometers to make them more useful for chemical analysis. Martin Packard was the R&D manager, and Ralph Kane the group manager. The group was called Special Products, later called the Instrument Division, and currently called Nuclear Magnetic Resonance Instruments. At that time there was little structure and quite a bit of freedom. Jim Shoolery ran an NMR chemical applications lab, and he had an endless thirst for improvements of all kinds. We also got suggestions and feedback from customers visiting the applications laboratory and attending the NMR workshops. We were aware of where improvements could be made and that these improvements would lead to more applications. It wasn't a blind 'Let's try something and see if it goes'. We had a good idea of the importance of certain areas and where to put the emphasis. The emphasis was on higher magnetic fields, greater sensitivity, better resolution, field/frequency stability and double resonance.

I put a lot of effort on designing current shims to improve the resolution. Because of the rather long relaxation times found in liquids, it became obvious to us that we could improve the resolution if we could make the magnetic field more uniform. In order to make the shims independent, Ed Jaynes¹⁶ had suggested winding them on the boundary of a sphere in a way that would make the shims correspond to the spherical harmonic mathematical expansion. This could be done easily for the proton free precession magnetometer where there was plenty of open space around the sample. However, in high-resolution spectrometers the sample was confined to a narrow region between two pole caps. After some thought, I designed and built a shim coil set that preserved the same mathematical relationship but would fit flat against the pole caps.¹⁷ This was an extension and improvement of the coil set that Jim Arnold and I used at Stanford several years earlier.

Another area that required attention was magnetic field inhomogeneities due to the finite magnetic susceptibility of the rf probe coils. Up to that time copper wire had been used to wind the probe coils. Although copper has a small magnetic susceptibility, because of its closeness to the NMR sample it can introduce high order magnetic field gradients, which are difficult or impossible to compensate for by the use of current shims. We couldn't find a suitable material with zero susceptibility so we used two closely spaced materials, one with positive susceptibility, the other negative, to yield a combination that behaved like a material with zero or near-zero susceptibility.¹⁸

Taming the spectrometer to sweep smoothly through a spectrum was another project that took on some importance. It turned out Jim Shoolery wasn't interested in opening and closing windows, turning on and off heaters, or adjusting knobs to control the changing random drifts that were particularly troublesome when sweeping slowly through the very narrow lines of a high-resolution spectrum. A number of ideas were proposed and evaluated before a suitable solution was found. In 1956 a flux stabilizer, called a 'Superstabilizer', was introduced which removed the rapid random fluctuations of the magnetic field strength. Russ Varian came up with the concept that led to the ultimate solution to the stability problem.¹⁹ His idea, shown in Figure 4, was to use one NMR line as a control to stabilize the field/frequency relationship of a sample group. He proposed using a control line as part of a feedback loop in an oscillator so its frequency would be determined by the resonance condition of that line. This frequency could then be used to stimulate the resonance of the sample group. Since the two samples were separated in space, a small field-sweep coil could be used to sweep through the resonance of the sample group. A number of related schemes were

Figure 4 Drawing showing a method to stabilize the field/frequency relationship in an NMR spectrometer. (From Russell Varian, *US Pat. 3 109 732*; Ref. 19)

developed for achieving field/frequency stability that utilized a stabilizing control line either in the same sample or in a different sample.²⁰ In the late 1950s an accessory was offered to provide the field/frequency stabilization system to the high-resolution NMR spectrometers. One variation on Russ's NMR oscillator that I had developed, called the sideband oscillator,²¹ was used in the Varian A-60 spectrometer. This was Varian's first analytical NMR spectrometer. It incorporated the use of precalibrated recorder chart paper and an integrator as standard features. The use of high-frequency field modulation also provides baseline stability which is particularly important when integrating NMR spectra.²¹

By going to higher values of magnetic field strength one gains both sensitivity and dispersion. During his graduate work at Stanford, Harry Weaver designed and built a 12-in. H-shaped electromagnet. His design formed the basis of the iron magnets that Varian sold and later incorporated into the early Varian NMR spectrometers. The first Varian high-resolution NMR spectrometers operated at a frequency of 30 MHz (approximately 0.7 T) and were designed for proton spectroscopy. Much effort was directed toward achieving higher magnetic field strengths using various pole cap materials, tapering the caps in various ways, narrowing the gap, and improving the current shims. By 1955 we were operating at 40 MHz. Then a project called SMOFF was started, which stood for Sixty Megacycles Or Fifty Five. Fortunately we met the 60 MHz goal in 1958. By the time we reached 100 MHz in 1962 we realized we were near the end of the line with iron magnets because of saturation of the iron.

After receiving his Ph.D. at Stanford, Harry Weaver spent two years at the University of Zürich and then in 1954 joined Varian in Palo Alto. Here he developed a high-resolution superconducting magnet system using a niobium–titanium alloy.²² The result was the Varian HR-200, the HR-220, and later the HR-300 high-resolution NMR spectrometers. To achieve still higher fields, a niobium–tin alloy is used in the central core of the magnet. Using magnets purchased from Oxford Instruments, Varian has produced NMR spectrometers 400, 500, 600, and now 750 MHz (17.6 T). Figure 5 is a graph showing the highest spectrometer frequency plotted versus the year of introduction. It is interesting to note the slope of the curve is quite steep during the iron magnet period (1953–1962), somewhat flatter for the niobium–titanium alloy period (1964–1972) and still flatter for the more difficult niobium–tin alloys currently used. I might speculate that in future years we will see 1000 MHz and above, perhaps using the new high transition temperature superconducting materials (but still operating near liquid helium temperatures).

Double resonance studies provided a way to get more information than a single sweep spectrum.²³ Spin decoupling experiments demonstrated the usefulness for simplifying spectra. When Ray Freeman arrived at Varian in 1961, he was anxious to extend some of the techniques for determining relative signs of spin coupling constants that he and Whiffen had started.²⁴ We worked out the double resonance patterns expected for a number of different spin configurations.²⁵ One of the ideas we explored was that of indirect detection of naturally abundant ^{13}C nuclei by modulation techniques²⁶ or the small splitting on proton lines as a weak rf frequency was swept through the carbon spectrum.²⁷ These techniques provided the sensitivity of the proton resonance while detecting

Figure 5 Plot of the maximum NMR spectrometer frequency versus year. The line segment at the left represents data for spectrometers with iron magnets; the right segment is for spectrometers with superconducting magnets

the position of the ^{13}C peaks. We also did the early experiments using multiple quantum transitions to help in high-resolution NMR spectra determinations.²⁸

I also worked with Larry Piette, who was the Jim Shoolery of EPR, and Jim Hyde, who was my counterpart in EPR. Jim worked on EPR instrumentation, and Larry worked on the chemistry applications. Forrest Nelson was an electrical engineer who contributed to many NMR and EPR ideas. Richard Ernst joined the group in 1963 and Howard Hill in 1968. The strong interaction among the various members of the group as well as interactions with the applications laboratory people provided a very stimulating atmosphere. It was a good environment for exploring ideas that could improve NMR and EPR spectroscopy, and make them more useful to the scientific community.

FOURIER TRANSFORM NMR

Perhaps the most important development that I participated in was that of Fourier Transform NMR or FT NMR. It was this development that speeded up NMR data collection by a factor of 1000 or more. This is another area in which the initial suggestions came from Russ Varian. He proposed²⁹ using a wide band set of frequencies to increase the sensitivity of NMR spectrometers. His method was to excite all of the lines in the NMR spectrum with a wide band noise source (see Figure 6). The resulting signals would then be heterodyned down to the audiofrequency range and recorded on magnetic tape. After the recording was completed, an endless tape would be made by pasting the end of the tape to the beginning. The endless tape would then be played back many times, each time mixing it with a different frequency. The mixer output would then be fed through a narrow band filter and recorded. Basically, it was a crude Fourier analyzer. Different mixing frequencies would select different signal frequencies and different parts of the NMR spectrum. The output of the detector represented the amplitude of a particular frequency component. This was a non-real-time system; however, the spectrometer could be getting new data while the analysis was being carried out on the old data.

One of the ideas I had was to generate each frequency by a separate oscillator, rather than use a noise source to produce a wide band of frequencies. By using separate oscillators, the individual frequencies would be coherent so that the same

Figure 6 Drawing showing the concept of wide band excitation and a Fourier transform detection system to increase the sensitivity of a high-resolution NMR spectrometer. (From Russell Varian, *US Pat. 3 287 629*; Ref. 29)

oscillator could be used to phase-detect each frequency. I proposed a rather simple way to generate and detect all of the frequencies simultaneously with an optical chopper wheel, called a 'Wheel of Fortune' by some and a 'Prayer Wheel' by the skeptics (Figure 7). It was a plastic cylinder about 6 in. diameter and 8 in. high, which was slowly rotated by an electric motor. The wheel contained about 20 cylindrical segments, each with a slightly different diameter. On each segment was placed a strip of a Ronchi grating (a photographic film of light and dark bands) with about 40 bands per inch. A light was placed inside the cylinder. A lens placed outside the cylinder would direct the light passing through each cylindrical segment onto a common photoelectric detector. As the wheel turned, each cylindrical segment would chop the light at a slightly different frequency, so the output of the photoelectric detector would contain all of these frequencies. This signal would then be mixed with a suitable offset frequency and transmitted to the probe to stimulate any NMR resonance signals.

This same wheel was used to separate the received NMR signals. The received NMR signals would be brought back into the audio range by mixing them with the same offset frequency. The resulting audiofrequency would then be applied

to a second light source within the wheel, but on the opposite side. This time the light would be demodulated by the series of light and dark bands on the wheel. After the light had passed through each segment, it would be collected on a separate photoelectric detector. The output of each photoelectric detector would then be fed to separate integrators, and the output of each integrator would correspond to one frequency component of the NMR spectrum. This system would operate in real time, with no delay for processing the signals.

Before this system was finished, a better idea came along of using pulses and computers instead of the wheel. Eventually, the chopper wheel was donated to the Smithsonian Institution as an example of one step in the evolution of an idea³⁰ (Figure 8).

The new idea was even closer to the original Fourier transform idea of Russ Varian. The wide band of frequencies is generated by a series of pulses applied to the transmitter frequency. The resulting frequencies, which are all coherent, are applied to the nuclei in the magnetic field to stimulate responses from the entire NMR spectrum. The stimulated resonances are brought into the audiofrequency range by

Figure 7 Excerpt from Anderson's notebook outlining the concept of the 'Prayer Wheel'

Figure 8 Anderson saying good-bye to the 'Prayer Wheel' as it departs for the Smithsonian

mixing them with the original rf frequency. The audio responses would then be digitized and stored by a computer of average transients (CAT) that was then commonly used to time-average NMR data (Figure 9). Richard Ernst built the apparatus and our first experiment gave us good data. However, using the technology of the day, we had to punch out the data on paper tape, convert the tape data to IBM cards, and take the cards to the Service Bureau Corporation on the other side of Palo Alto. Several days later, after waiting for payroll and factory inventory processing to be completed, the computer performed the Fourier transform step and plotted out the spectrum.³¹

As soon as possible, we ordered a minicomputer. By today's standards it was slow, and the 4000 bytes of memory trivially small; however, it enabled us to transform the data and plot it in a few minutes. With the advent of larger and faster computers and with the development of the Fast Fourier Transform (FFT) techniques by Cooley and Tukey, the transform has been speeded up considerably. Today even large

Figure 9 Excerpt from a page in Anderson's notebook outlining the idea of the FT NMR spectrometer

multidimensional transforms can be taken in seconds. Fourier transform changed the whole way of life in NMR. Varian offered an FT accessory for the HR-100 in 1968. Soon FT NMR almost completely replaced the former method of slowly scanning through the spectrum. From contributors throughout the world a whole new set of techniques have been developed to enhance further the capability of FT NMR.

THEN AND NOW

It is remarkable how far NMR has advanced during its 50 years of history. Much of the early progress can be traced to Russell Varian, from his early belief that NMR would be important to chemistry, his writing the original NMR patent, obtaining a licence under the patent, his insistence that his new company, Varian Associates, develop and commercialize NMR magnetometers and spectrometers, and because of the important technical contributions he made to the technique. He would be pleased to see how far NMR has developed in the intervening years since his death in July 1959. It has been exciting for me to play a small role in furthering the development of NMR instrumentation and to extend its usefulness.

In 1972 I was named Director of the Varian Systems and Techniques Laboratory and became involved in other research activities. My initial activity in this new laboratory was the development of ultrasound equipment for real time medical imaging of the human heart—but that's another story.

Improvements of NMR instruments continued, building upon the earlier work. In 1974 Richard Ernst, now back at the Federal Institute of Technology (ETH) in Zürich, followed a proposal of Jeener³² to demonstrate a new two-dimensional (2D) technique.³³ A second frequency dimension was introduced and a second FT used to extract additional NMR data. In 1975, Ernst proposed an FT method of acquiring and reconstructing MRI data³⁴ that is analogous to the 2D spectroscopy method. For these two achievements and our earlier work with FT NMR he was awarded the 1991 Nobel Prize in Chemistry.

Today FT NMR is playing an indispensable role in medicine with MRI instruments and a crucial role in spectroscopy as a tool for chemists and biologists. All signs point to continued development leading to a still brighter future.

Ando, Isao: Structures and Electronic States of Polymers as Studied by High-Resolution NMR Spectroscopy Combined with Quantum Chemistry

Isao Ando

Tokyo Institute of Technology, Tokyo, Japan

Since Gutowsky et al.¹ observed the 18 MHz ¹H high-resolution NMR spectrum of uncured Heva rubber (polyisoprene) in CS₂ in 1957, high-resolution NMR spectroscopy has developed to become the most powerful method available for characterizing the structures and dynamics of synthetic polymers in the solution and solid states. Nishioka et al.² and Bovey et al.³ separately determined the stereochemical structure of poly(methyl methacrylate) prepared by radical polymerization and anionic polymerization by means of high-resolution ¹H NMR spectroscopy. These studies have provided great influences in the research fields of structure and stereospecific polymerization in polymer science.⁴ In addition, Schaefer et al.⁵ have recently successfully measured the high-resolution solid state ¹³C CP MAS (cross polarization/magic angle spinning) NMR spectra of polymers in the solid state. This leads to the elucidation of structure and dynamics of polymers in the solid state.

Nevertheless, in order to provide a deeper insight into molecular structures and electronic structures of polymers, more sophisticated approaches might be developed in high-resolution NMR spectroscopy. The NMR chemical shift should provide detailed information about the structure and electronic state of polymers in the solution state and the solid state if high-resolution NMR spectroscopy is combined with quantum chemistry.^{6,7} The chemical shifts of the nuclei in polymers depend on their magnetic environment which depends on the stereochemical configuration and higher-order structure such as conformation and crystal structure of the polymer chains.

My co-workers and I have developed a methodology for obtaining stereochemical configuration and higher-order structure, and the electronic states of polymers both in the solution^{6, 8–13} and solid state^{7, 14–23} through a combination of the observation and calculation of NMR chemical shifts, and have applied this to various polymer systems. Theoretical calculations of NMR chemical shifts for polymer systems have been done mainly by two approaches. One is that model compounds such as the dimer, trimer, etc., as local structures of polymer chains, are used in the calculation by combining quantum chemistry and statistical mechanics.^{6, 8–13} In particular, this approach has been applied to polymer systems in the solution state. However, in solid polymer systems it sometimes has to be recognized that the results of quantum chemical calculations on model compounds are not readily transferable to polymers because of differences in electronic structure, including long-range interactions such as intrachain interactions and interchain interactions. Electrons

are constrained to a finite region of space in small molecules whereas this is not necessarily the case for polymers, and for this reason some additional approaches are required. Another approach is to employ the tight-binding molecular orbital (TB MO) theory,²⁴ which is well known in the field of solid state physics, to describe the electronic state of linear polymers with periodic structure within the framework of the linear combination of atomic orbitals approximation for the electronic eigenfunctions.^{7, 14–23} These approaches have led to the determination of the structure and/or electronic state of polymer systems including polypeptides in the solution state and solid state. The essence of these two approaches will be described below.

APPROACH USING MODEL COMPOUNDS

A polymer chain can assume an enormous number of conformers because of the various possibilities of rotation around the chain bonds. Thus the factors governing the appearance of the NMR spectra include stereochemical configurations, the relative energies of the rotational isomers, the chemical shifts, and spin couplings. If molecular motion in the polymer chain is slow, the spectrum represents the superposition of the spectra for the various conformations. However, if the rotation around the chain bonds is very fast on the NMR timescale, the experimentally observable chemical shift for nucleus A is given as:

$$\langle\sigma_A\rangle = \sum_{i=1}^n P_i \sigma_i \quad (1)$$

The numerical indices refer to the preferred conformers, and P_i and σ_i are the probability of occurrence and the chemical shift of the preferred conformer i , respectively. This indicates that the chemical shift of a given nucleus in a polymer chain in the solution state can be calculated by means of a combination of a quantum chemical method²⁵ and a statistical mechanical method²⁶ as described below. The chemical shift of an atom depends upon its electronic and molecular environments. The chemical shift for atom A can be estimated by a sum of the following terms:²⁵

$$\sigma_A = \sigma_d + \sigma_p + \sigma' \quad (2)$$

where σ_d is the diamagnetic term, σ_p is the paramagnetic term, and σ' is another term which comes from the magnetic anisotropy effect, polar effect, and ring current effect. For nuclei with 2p electrons such as ¹³C, ¹⁵N, etc., the relative chemical shift is predominantly governed by the second term, and for the ¹H nucleus by the first and third terms. The paramagnetic term is expressed as a function of excitation energy, bond order, and electron density according to the sum-over-state (SOS) method in the simplest form as follows:²⁵

$$\sigma_p = -C \sum \langle r^{-3} \rangle_{2p} (E_m - E_n)^{-1} Q \quad (3)$$

where $E_m - E_n$ is the singlet–singlet excitation energy of the n th occupied and the m th unoccupied orbitals, and Q is a factor including the bond order and electron density.

Figure 1 The planar conformation of any specified configuration of a vinyl polymer

Figure 2 Newman projections of the rotational isomeric states about the $(i - 1)$ th bond in Figure 1. T depicts *trans*, G and G' two *gauche* conformations; η , 1 and τ are statistical weight factors

The quantity $\langle r^{-3} \rangle_{2p}$ is the spatial dimensions for a 2p electron while C is the coefficient incorporating the universal constants. In the estimation of σ_p the finite perturbation theory (FPT)²⁷ has frequently been used. The diamagnetic term is estimated from the calculated electron density. Using these procedures, the chemical shift σ_i of the model compound with any specified conformation is calculated. We sometimes have cases where solute–solvent interactions play an important role in an understanding of the chemical shift behavior. We have developed a method of calculating nuclear shielding by incorporating the FPT method and reaction field type solute–solvent interactions.^{11, 28–30} This approach reasonably explains the experimentally observed solvent effects on chemical shift (and also the spin–spin coupling constant³¹).

The probabilities P_i of the preferred conformations in various configurations in vinyl polymers as a function of the racemic units necessary for the calculation of the averaged chemical shift (σ) is estimated by statistical mechanics for a polymer chain. For convenience, the planar conformation in any specified configuration of a vinyl polymer is shown in Figure 1. Newman projections of the rotational isomeric states about the $(i - 1)$ th bond are given in Figure 2.

The statistical weight matrices for the characterization of the array of chain conformations of vinyl polymers can be used.²⁶ The purpose of calculating the probability that the pairs of skeletal bonds within the k th dyad, the k th triad, and so on in a chain are in particular rotational states is that such statistical weights are used to construct statistical weight matrices $\mathbf{U} = \mathbf{U}'\mathbf{U}''$. In such matrices, rows are associated with rotational states about bond $i - 1$ and columns with rotational states about bond i . The complete statistical weight matrices in the case of pairs of bonds adjoining CHR groups are designated $\mathbf{U}''$. These matrices are expressed as

$$\mathbf{U}' = \begin{pmatrix} \eta & 1 & \tau \\ \eta & \omega & \tau \\ \eta & 1 & \tau\omega \end{pmatrix} \quad (4)$$

for the first skeletal bond of a dyad and

$$\mathbf{U}_m'' = \begin{pmatrix} \eta\omega & 1 & \tau\omega \\ \eta & \omega & \tau\omega \\ \eta\omega & \omega & \tau\omega^2 \end{pmatrix} \quad (5)$$

$$\mathbf{U}_r'' = \begin{pmatrix} \eta & \omega & \tau\omega \\ \eta\omega & 1 & \tau\omega \\ \eta\omega & \omega & \tau\omega^2 \end{pmatrix} \quad (6)$$

for the second; the former matrix, equation (5), is for a *meso* dyad and the latter [equation (6)] for a racemic one. The statistical weight factors 1, η , and τ are defined in Figure 2. The configuration partition function Z for the entire chain can be expressed as the sum of the statistical weights for all molecular conformations of the chain consisting of n bonds or $x = 1/2 n$ repeating units

$$Z = \mathbf{J}^* \left(\prod_{i=1}^{n/2-1} \mathbf{U}_i' \mathbf{U}_i'' \right) \mathbf{J} \quad (7)$$

where $\mathbf{J}^* = (1 \ 0 \ 0)$ and $\mathbf{J}$ is the transpose of $(1 \ 1 \ 1)$. Let β and γ denote indices from the set T , G , and G' . The probability $P_{\beta\gamma:k'}$ that the pair of skeletal bonds within the k th dyad are in the rotational states β and γ , respectively, is the ratio of the sum of the statistical weights for all conformations. It is given by

$$P_{\beta\gamma:k''} = Z^{-1} \mathbf{J}^* \left(\prod_{h=1}^{k-1} \mathbf{U}_h' \mathbf{U}_{h+1}'' \right) \left(\mathbf{U}_k' \mathbf{U}_{(\beta\gamma)k}'' \right) \left(\prod_{i=k+1}^{x-1} \mathbf{U}_i' \mathbf{U}_{i+1}'' \right) \mathbf{J} \quad (8)$$

in which $\mathbf{U}_{(\beta\gamma)k}''$ is the matrix representing the second bond of the k th dyad with all of the elements, except $\mathbf{U}_{(\beta\gamma)k}''$, replaced by zero. $P_{\beta\gamma:k'}$ is estimated by generating Monte-Carlo chains. An averaged chemical shift is then obtained using the values obtained for $P_{\beta\gamma:k'}$ and σ_i .

Using this developed methodology, the structural behaviors of polyethylene and n -paraffins, vinyl polymers such as poly(vinyl chloride) and polypropylene, poly(L-alanine), etc. in the solution state have been successfully elucidated on the basis of their observed spectra.^{6, 8–13} We demonstrated that such approaches for polymer systems in the solution state provide useful explanations of the observed spectra, conformational behavior, and assignments of resonances to the configurational structures such as a dyad, triad, tetrad, and so on.

In the crystalline state polymer chains assume a fixed conformation. In this case, the structural information obtained from the chemical shift corresponds to the fixed conformation. The calculation of ^{13}C chemical shifts for a dipeptide fragment of poly(L-alanine) has been attempted using the FPT INDO method in order to understand and predict the ^{13}C chemical shift behavior of polypeptides associated with a secondary structure such as an α -helix, β -sheet, etc., and the determination of secondary structure through the observation of the ^{13}C chemical shift.³² The ^{13}C chemical shifts of the C_β carbon of an alanine residue in various peptides and polypeptides vary significantly depending on the conformation, which may be a right-handed α -helix, β -sheet, or other conformation. Such

Figure 3 The calculated ^{13}C chemical shift contour map of C_β in *N*-acetyl-*N'*-methyl-L-alanine amide obtained using the FPT INDO method. The chemical shifts were calculated at 15° intervals for Φ and Ψ

sizeable displacements of the ^{13}C chemical shifts can be characterized by variations in the electronic states of the local conformation as defined by the dihedral angles (ϕ, ψ) . The calculated contour map for the C_β carbon is shown in Figure 3. From this map, we can estimate the ^{13}C shielding for any specified conformation. It has been demonstrated from comparisons of the experimental data and the predicted values given by this contour map that the map successfully predicts the ^{13}C chemical shifts of alanine residues in polypeptides and proteins.^{33,34} (It should be noted that the negative sign of the shielding constant σ indicates deshielding and so shielding variations can be compared with the observed chemical shift δ where a positive sign denotes deshielding.) Such calculations are very useful as a means of analyzing the structures of polymers.

Most recently, the linear relationship between the ^{13}C chemical shift and hydrogen bond length of the carbonyl carbon in glycine and alanine residues of peptides in the solid state has been clarified.^{35–37} This result has been justified by FPT INDO calculations. The observation of the chemical shift of the glycine and alanine residue carbonyl carbons of peptides in the solid state allows a determination of the hydrogen bond length. Such experimental findings help to refine the hydrogen bond lengths in proteins as determined by X-ray diffraction.³⁷ Furthermore, ^{15}N NMR experiments provide very useful information about the structure of peptides and polypeptides in the solid state through the assistance of nuclear shielding calculations.³⁸

APPROACH OF USING INFINITE POLYMER CHAINS

Sometimes the estimation of the electronic states of polymer chains necessitates the inclusion of long-range interactions and intermolecular interactions in the calculations. To do this, it is necessary to use a sophisticated theoretical method which can

take account of the characteristics of polymers. In this context, the tight-binding molecular orbital (TB MO) theory from the field of solid state physics is used, in the same sense in which it is employed in the LCAO approximation in molecular quantum chemistry to describe the electronic states of infinite polymers with a periodic structure. In a polymer chain with linearly bonded monomer units, the potential energy of an electron varies periodically along the chain. In such a system, the wavefunction Ψ for electrons at a position r can be obtained from Bloch's theorem as follows:

$$\Psi(k) = N^{-1/2} \sum_{j=-(N-1)/2}^{(N-1)/2} \sum_{v=1}^s e^{-ikja} C_{vn}(k) \phi_v(r - ja) \quad (9)$$

where k is the wavenumber, n is the band index, v is an orbital index in the j th cell, a is the unit vector of translational symmetry, N is the total number of cells, and l is the number of atomic orbitals in the cell. The term $\phi_v(r - ja)$ represents the v th atomic orbital in the j th cell and $C_{vn}(k)$ the expansion coefficient. The formulas needed to calculate the shielding of polymers using the TB MO theory incorporating the SOS method have been derived as a function of k as follows:^{14,15}

$$\sigma_d(k) = C \sum P(k) \langle \phi_v(r) | r^{-1} | \phi_v(r) \rangle \quad (10)$$

$$\sigma_p(k) = -C' \sum \langle r^{-3} \rangle_{2p} [E_m(k) - E_n(k)]^{-1} Q(k) \quad (11)$$

where C and C' are constants and $P(k)$ is the bond order as a function of wavenumber. The nuclear shielding is calculated as a function of k . In order to compare the calculated and experimental values of the nuclear shielding, it is necessary to average the calculated data over k , within the first Brillouin zone, as given by

$$\sigma = \int_{-\pi/b}^{\pi/b} \sigma(k) D(k) dk \quad (12)$$

where $D(k)$ is the density of states, namely the number of states per unit amount of energy.

Using this methodology, the elucidation of conformation-dependent chemical shifts of various polymer chains such as polyethylene, polyacetylene, polypyrrole, polyoxymethylene, and polyoxyethylene in the crystalline state has been studied systematically.^{7, 14–23} For example, a comparison of the experimental data and the TB INDO/S calculation of the ^{13}C chemical shift tensor of *cis*- and *trans*-polyacetylene in the solid state is shown in Figure 4. The directions of the principal axes are indicated at the bottom. These results agree well with the experimental data.

This shows that the TB MO calculation correctly predicts the origin of the chemical shift and electronic state associated with the structure of the polymers. Furthermore, TB INDO/S calculations have been carried out on the seven polyacetylene chains which take an orthorhombic form. From these results it has been demonstrated that the chemical shift is very sensitive to intermolecular interactions and the TB MO calculation provides useful information about the band structure. The TB MO calculation on the ^{15}N chemical shift of polypyrrole in the solid state allows useful information to be extracted from

Figure 4 The observed and calculated components of the ^{13}C shielding tensors of *cis*- and *trans*-polyacetylene. The directions of the principal axes are indicated at the bottom (the angles between the C-H bond and the direction of σ_{zz} for *trans*- and *cis*-polyacetylene are 16° and 17° respectively)

the observed spectra, namely that the two peaks obtained are correctly assigned to the quinoid and aromatic structures.²⁴ (The quinoid structure is closely related to the electric conductivity.) A decrease in the band gap leads to a downfield shift. These results on conducting polymers demonstrate that the chemical shift behavior provides information about the band gap which, in turn, is a measure of the electrical conductivity. It can be said that TB MO calculations offer useful perspectives in interpreting the results of NMR nuclear shieldings in polymers, both in terms of the structure in the solid state and in understanding the effect of intermolecular interactions on nuclear shieldings. The latter are shown to operate through the electronic states of the polymers considered. The above-mentioned research work has already been presented in a number of review articles.

Finally, NMR in Japan should be mentioned. There are a number of research groups for NMR, the largest being the Research Group of NMR in Japan which organizes a domestic NMR symposium every autumn to which foreign speakers are invited. The Research Group of NMR in Japan was established in 1961 by the NMR spectroscopists Professors S. Fujiwara, A. Nishioka, A. Saika, and T. Yonezawa amongst others. The number of presentations is about 100 per meeting, and the number of participants is normally about 500. The field of these presentations is NMR techniques, NMR theory, organic chemistry, inorganic chemistry, physical chemistry, polymer science, natural products, biochemistry, solid state NMR, and NMR imaging. The NMR Research Group in the Society of Polymer Science, Japan was established in 1977. The number of members is about 100. Meetings are organized twice every year and about five speakers are invited. The number of participants is about 40. A workshop is open for NMR beginners every year, mainly drawn from the Institute of Industries. Recently, the development of NMR imaging has led to the establishment in 1981 of the Society of Magnetic Resonance, Japan associated with the field of medicine. The number of members is about 3000. Superconducting NMR instruments are available at many universities, public institutes,

and industrial research centers in Japan. It is estimated that the number of superconducting NMR instruments is about 1200. The number of MRI machines found in hospitals is over 800. As a result, many NMR seminars are organized in Japan.

Biographical Sketch

Isao Ando, *b* 1941. Ph.D., (supervisor Atsuo Nishioka) 1972, Polymer Chemistry, Tokyo Institute of Technology, Japan. Postdoctoral work at University of Illinois, Urbana (with Herb Gutowsky). Successively research associate, associate professor, and professor, Tokyo Institute of Technology. Approx. 250 publications. Research specialities: structures and electronic states of solid polymers, solid state NMR, and nuclear shielding calculations.

Andrew, E. Raymond: Spinning the Spins: A Lifetime in NMR

E. Raymond Andrew

University of Florida, Gainesville, FL, USA

It happens that my professional life spans the first 50 years of NMR that we are celebrating in this volume. It is a most wonderful evergreen subject with a continual supply of new and exciting developments, and I have been most fortunate to have had the opportunity to participate in some of them.

I first heard about nuclear magnetic resonance in 1946 when I was a research student in the Cavendish Laboratory at Cambridge University, working for my Ph.D. on problems in superconductivity with Professor David Shoenberg. Whenever something of interest caught David's eye in the literature he would depute one of us to read it up and present a talk at the weekly low-temperature seminar. In this way I read the first publications of Bloch¹ and Purcell² and their colleagues. Then in 1947 Professor Bloch paid a visit and gave a fascinating talk and in 1948 Bloembergen and Pound came through. It was clear that NMR was an exciting new subject and when applying to the Commonwealth Fund for a postdoctoral fellowship, I proposed to work on NMR at Harvard.

The first British pioneer in NMR was Dr. Bernard Rollin at Oxford University, so before leaving Britain for my postdoctoral year in America, I visited him at the Clarendon Laboratory. Immediately after seeing the first NMR publications in early 1946, he had built a very simple and elegant NMR spectrometer of novel design, and by November 1946, he had published his first NMR paper in *Nature*³ announcing detection of proton and fluorine NMR in a range of liquids and solids and had measured their relaxation times. The next year, 1947, he undertook the first low-temperature NMR, measuring T_1 and T_2 in liquid and solid hydrogen and other materials down to 1 K.⁴ His work is less widely known than it deserves to be partly because he would never travel outside Oxford. In fact he would only speak at a conference if the conference was held in Oxford!

I was very fortunate to spend my postdoctoral year, 1948–49, working in the laboratory of Professor E. M. Purcell at Harvard University. He is a truly remarkable scientist with wide interests beyond NMR ranging from astrophysics (with his student Ewen he first discovered, in 1951, the 21-cm hydrogen hyperfine line from outer space) to biophysics (in 1984 he was jointly awarded with Howard Berg the APS Biological Physics prize for the elucidation of bacterial locomotion). He is also an extraordinarily pleasant person and, as I write in 1993, is still active, going daily to the Lyman lab at Harvard at the age of 81. Photographs of some scientists mentioned in the text, including E. M. Purcell, are given in Figure 1.

In my application to the Commonwealth Fund I had proposed to study the NMR linewidth at phase transitions in solids where specific heat measurements suggested the possible onset of molecular rotation. An alternative technique for the study of molecular reorientation in solids was dielectric

dispersion, but that requires molecules with a permanent electric dipole moment which are inherently asymmetrical. It seemed to me that the beauty of NMR was that one could examine symmetrical molecules like benzene which were more likely to rotate in the solid state, even though the specific heat showed no anomaly. Unknown to me when I made my proposals, Herb Gutowsky and George Pake were completing theses at Harvard in Ed Purcell's lab on the ammonium halides and methyl groups, so my research proposals fell on very receptive ears. I spent a marvelous year in his laboratory working on NMR in solid long-chain paraffins, solid benzene, and various solid methylbenzenes.⁵ Solid benzene, in particular, provided an excellent example of reorientation about its sixfold axis in the solid state.

I had a laboratory on the basement floor of the Lyman Laboratory and in the next lab was one of Ed Purcell's graduate students, Charlie Slichter, now a Professor at the University of Illinois. There was a large rectangular hole in the communicating wall about 1 m wide, 0.3 m high, put there by a previous occupant who needed a long light path. Charlie and I got to know each other well through that hole in the wall, and I'm very happy that our paths have crossed frequently in recent years as officers of ISMAR. My continuous-wave NMR spectrometer (see photograph in Figure 2) consisted of a permanent magnet, a General Radio signal generator, an rf bridge and preamplifier, a Hallikrafters receiver, an output meter, and an oscilloscope.

A condition of the Commonwealth Fund Fellowships, a far from irksome condition, was the requirement that we travel around the United States for three months and take back our experiences and impressions to Britain. During April to July of 1949, we covered 20 000 km in a pre-war Ford; I learnt a lot about cars as well as NMR that year. We visited NMR labs and low temperature labs. I had the great pleasure of meeting Henry Torrey at Rutgers, Felix Bloch at Stanford, and W. F. Giaque at Berkeley. I came to know Felix quite well over the years and visited him several times including 1983, shortly before his death. He obtained his doctorate at Leipzig and had a fund of stories about Heisenberg who was Professor of Theoretical Physics there, and about Boltzmann who previously held the same Chair. Just down the road at MIT I had several meetings with Francis Bitter who made some early contributions to NMR.⁶ At Harvard itself there were many famous physicists at work, including Van Vleck,⁷ who had just written his classic second and fourth moment paper, Bob Pound pioneering quadrupole interactions⁸ in NMR, Bloembergen who had just returned from Leiden during my year, Ramsey setting up his new high-resolution atomic beam magnetic resonance system, and Bridgman still working in his retirement on physics at high pressures.

In 1949, I returned to Britain after this splendid year in America and took up an academic appointment as a lecturer at St. Andrews University, the oldest university in Scotland. With the enthusiastic encouragement of our Head of Department, Professor Jack Allen, we set about constructing an NMR spectrometer. Alwyn Rushworth and I designed a 0.6 T permanent magnet and had it built in Sheffield. At 2 tons it was the largest permanent magnet in Britain at the time. My first research student, Bob Eades, helped me build the NMR spectrometer. Our first projects centered on molecular dynamics in solids measuring spin–lattice relaxation times T_1 over a wide temperature range, supplemented by second

Figure 1 Some scientists mentioned in the text: (a) F. Bloch; (b) E. M. Purcell; (c) C. J. Gorter; (d) A. Kastler; and (e) E. K. Zavoisky.

moment analysis. We examined solid cyclohexane⁹ and solid benzene¹⁰ in depth, determining the kinetics of a variety of modes of reorientation and in solid cyclohexane finding the first unequivocal evidence of molecular diffusion in the solid state by NMR.

Soon after the publication of my first NMR paper in the *Journal of Chemical Physics*, a letter arrived from Professor Alfred Kastler in Paris. He had earlier measured the Raman spectrum of solid benzene and wondered how our work could be compatible with his. After all, if the molecules were rotating about their hexad axes, how could a Raman spectrum be found from hexad librations? He was most interested in my explanation that by NMR we measured the relatively infrequent reorientations of the molecules while he was measuring the rotational oscillations between these events.

Soon afterwards he invited me to lecture in Paris, so beginning a long friendship until his death in 1984. He was awarded the Nobel prize in 1966 for discovering optical methods for studying radiofrequency resonances in atoms.

Not only does NMR give dynamical information concerning the solid state but it also gives structural information, especially about hydrogen atoms as George Pake had demonstrated in a classic experiment on hydrates.¹¹ NMR and X-ray diffraction complement each other. Hydrogen, the one element on which X-ray diffraction is silent, is the element on which NMR is most articulate. Urea was a molecule of substantial biophysical significance; its X-ray structure was known, giving the positions of the four heavier atoms in the molecule, but the placing of the four hydrogen atoms was a matter of controversy in the literature. Was the molecule planar or nonplanar?

Figure 2 (a) The author in his NMR laboratory at Harvard University, 1949. Note the hole in the wall to the laboratory of C. P. Slichter. (b) E. R. Andrew (President) and C. P. Slichter (Vice-President) at the ISMAR Conference in Rio de Janeiro 1986.

My student, Dan Hyndman, patiently grew some single crystals and we were able to show unequivocally from the proton NMR spectra and second moments that the planar form was correct,¹² and we determined the bond lengths to 1% with evidence of hydrogen bonding to neighboring oxygen atoms. Later this structure was confirmed by neutron diffraction. We liked to point out how much cheaper it was to gain structural information by NMR than by neutron diffraction!

About this time in Oxford, Rex (now Sir Rex) Richards began his early pioneering applications of NMR in chemistry. This eventually developed into an important school of high-resolution NMR spectroscopy in chemistry and biochemistry. One of Rex's students, Ray Freeman, returned to Oxford after working for some years at Varian Associates in California and later became Professor of NMR Spectroscopy at Cambridge University.

While we were in St. Andrews we were delighted to hear that the 1952 Nobel Prize for Physics had been awarded to Professors Felix Bloch and Ed Purcell. Very shortly afterwards it was a pleasure to welcome Ed to St. Andrews, and we were also very happy to have a visit from Bob Pound. Another welcome visitor was a young Japanese theorist called Kazuhisa

Tomita, who was then working on the famous relaxation paper by Kubo and Tomita;¹³ we met from time to time over the years until his death in 1991. Our NMR work had begun to attract some attention and in 1952 I was very pleased to be elected a Fellow of the Royal Society of Edinburgh. This old-established society is the Academy of Arts and Sciences of Scotland and had been presided over in earlier years by Sir Walter Scott and Lord Kelvin.

Many physicists and chemists were now taking an interest in NMR and there was a need for a book on the subject. I wrote my book *Nuclear Magnetic Resonance*¹⁴ in St. Andrews in 1953–54 and it was published by Cambridge University Press the following year. When my first royalty cheque for \$50 arrived, I remember calculating that this represented a rate of pay of about sixpence (about 5 cents) per hour spent on the project! Happily as the sales built up, the rate became somewhat more respectable.

My stay in Scotland, the land of my grandfathers, was five years and in 1954, I moved to the University of Wales at Bangor as Professor of Physics and Head of Department. NMR was a good subject to pursue in a small department with limited financial resources but plenty of talent. Bob Eades rejoined me as a lecturer after postdoctoral work in Vancouver; we had a long collaboration and built an active NMR group. Among many international collaborators was Dr. (now Professor) Jacek Hennel, who visited us for a year from Krakow, Poland, the first of many mutual visits. We had visits too from Abragam from Paris and Hahn from Berkeley.

In Wales we became interested in quadrupole-split spectra and Kenneth Swanson¹⁵ and I established a method for distinguishing quadrupolar from dipolar relaxation mechanisms in solids. David Tunstall and I derived the $2I$ relaxation times for nuclei of spin I for quadrupolar relaxation mechanisms in solids.¹⁶ This analysis has turned out many years later to be useful in current work on the new high-temperature superconductors where several of the elements of interest have quadrupolar nuclei of high spin. As physicists we were aware that in crystals, even cubic crystals, most physical properties are anisotropic. This led us to establish the anisotropy of T_1 in a number of ionic crystals and to relate this anisotropy to relaxation theory.¹⁷ We were also able to establish the anisotropy of chemical shift for ^{19}F in several molecular solids.

An important new interest emerged from our work in Wales which led us to discover magic angle spinning. It arose from the resolution of an NMR paradox. Molecular motion in a solid narrows the NMR spectrum and reduces its second moment to new plateau values as the temperature is raised. Yet according to Van Vleck's theory, the second moment should remain invariant. My solution to this paradox was that the reduced second moment came from the time-averaged dipolar Hamiltonian and that the time-dependent part generated weak unobservable satellite wings in the spectrum which, if included, maintained the invariance of the second moment. Detailed theoretical analysis confirmed this. However, it is never very satisfying to have to rely on something unobservable, so how could these weak satellites be made observable? It seemed to me that if we were to rotate a specimen rapidly we could simulate the effect of molecular motion on the dipolar interactions, but since all nuclear pairs would be rotating at the same rate the satellites would appear at the same frequency and be observable. Our first successful sample spinning experiment was reported in *Nature*¹⁸ in

1958, confirming the invariance of the second moment and demonstrating the satellite lines (spinning sidebands). Analysis showed that this line narrowing by rapid rotation should follow a factor $|\frac{1}{2}(3\cos^2\beta - 1)|$, where β is the angle between the axis of spin and the main magnetic field. It follows that when $\cos^2\beta = \frac{1}{3}$, or $\beta = 54^\circ 44'$ (the magic angle), dipolar interactions should be removed entirely from the central spectrum. We reported our confirmation of this in *Nature*¹⁹ in 1959. Unknown to us Irving Lowe²⁰ carried out a similar experiment independently in St. Louis, also reported in 1959. Later, in 1969, Irving came to spend a sabbatical year in Nottingham and he lived in my house while I was on leave at the University of Florida.

When we reported our first sample rotation results at the AMPERE Congress in Pisa in 1960, Professor Gorter of Leiden found the removal of the dipolar broadening of the NMR lines quite remarkable and referred to it as 'magic', so we called the technique 'magic angle spinning' after that. We showed theoretically that magic angle spinning removes broadening arising from any bilinear tensor interaction and we subsequently demonstrated this experimentally for dipolar and pseudodipolar interactions, for chemical shift anisotropy, and for quadrupolar interactions.²¹ With this technique we resolved the first spin multiplets in solids,²² in polycrystalline sodium hexafluoroarsenate and hexafluoroantimonate. We also resolved a number of chemically-shifted lines in solids. We went on to apply magic angle spinning to metals. The NMR lines of metals such as aluminum,²³ cadmium, and copper were narrowed by two orders of magnitude enabling the Knight shifts to be measured to a precision two orders of magnitude greater than hitherto. In copper we were able to measure the weak Ruderman–Kittel interactions,²⁴ normally obscured by the larger dipolar interaction, and to relate them to theory.²⁵

Magic angle spinning required very high rotation speeds. When visiting Professor R. M. Davies at our sister college in Aberystwyth, I noticed that he was spinning an octagonal mirror fast with the aid of a simple air turbine made of steel. This gave me the idea to fashion an air turbine made of nylon or other strong polymeric nonmetallic material, enclosing a specimen chamber. Our rotors spun to 10 kHz routinely and occasionally to 15 kHz. The peripheral velocity of a 19-mm diameter rotor rotating at 10 kHz is 2000 km h^{-1} , which is supersonic. Consequently for the highest rotation rates the rotors were driven with compressed helium;²¹ the velocity of sound in helium is 2.7 times higher than in air. The peripheral acceleration at 10 kHz is $4 \times 10^6 g$ and it was therefore necessary to use the strongest available materials to fashion the rotors. The world expert on high-speed rotation was Professor Jesse Beams of the University of Virginia. He invited me to visit his laboratory and I must confess I was pleased when he commented we had done well! Magic angle spinning has now become a standard feature of NMR spectrometers enabling chemists and others to obtain high-resolution NMR spectra from solid materials of all kinds. Nowadays spinning rates twice as fast as ours are obtainable using rotors of smaller diameter.

We had some tall people in the magic angle spinning team. Arnold Bradbury, 6 ft. 8 in., was one of the pioneer group; he joined the academic staff in the University of Wales and is still there. Geoffrey Jenks, 6 ft. 5 in., joined us soon after from Australia, after his Ph.D. returning to Melbourne. Gwynfor Williams, 6 ft. 3 in., was one of the invaluable

workshop technicians who made precision rotors. The Physics Department had an outstanding basketball team at that time which carried all before them in the University championship.

As momentum gathered in the applications of magnetic resonance in physics and chemistry, a forum was needed to enable practitioners to discuss their progress, their methods and new results. In France the Groupement AMPERE had been founded in 1952 for such a purpose, but its proceedings were at that time wholly in French. So, in 1956, we launched the British Radiofrequency Spectroscopy Group at an inaugural meeting at the University of Wales in Bangor. I was Chairman of the BRSG for its first three years and 25 years later I was again asked to be Chairman and to organize a jubilee meeting in Nottingham in 1981. I am delighted to record that 38 years later the BRSG is still a very active organization with a regular program of meetings, which have been held in all parts of Britain and also in Dublin and Paris. BRSG not only covers nuclear magnetic resonance but also electron spin resonance and other branches of radiofrequency and microwave spectroscopy. ESR had been discovered a year earlier than NMR by E. K. Zavoisky²⁶ in Kazan, Russia, in 1944, quite astonishingly at the height of the Second World War. So ESR celebrated its 50th anniversary in 1994, a year ahead of NMR.

After 10 years in Wales, I accepted an invitation to return to England in 1964 as Lancashire–Spencer Professor of Physics and Head of the Department of Physics at Nottingham University. A large new physics building with much new equipment provided a wonderful opportunity. Several new academic appointments were possible and a strong NMR group was assembled, now all professors: Stanley Clough, who accompanied me from Bangor and later became Head of Department, Peter (now Sir Peter) Mansfield, Peter Allen, now Head of Applied Sciences in Medicine at the University of Alberta, and Bill Derbyshire now at Rank–Hovis–MacDougall. Dr. Bill Moore also joined our NMR activities later, before his move to Harvard, where very sadly he died in 1984.

The move to Nottingham in 1964 saw a change in our NMR methodology. Pulsed methods gave a new dimension to NMR measurement enabling relaxation to be investigated more readily with accurate determination of all NMR parameters T_1 , $T_{1\rho}$, T_{1D} , T_2 , M_2 , D ; the spin system evolves freely between excitations, and the free induction decay could be Fourier-transformed to give the NMR spectrum. The broad NMR spectra from solids, especially from ^1H and ^{19}F , meant that a 90° pulse had to be as short as $1 \mu\text{s}$ and correspondingly of high intensity. A grant from the Science Research Council enabled us to purchase the first Bruker 1–100 MHz short pulse NMR spectrometer for solid state work in Britain. Very stable electromagnets were now available. The days when we designed and made our own spectrometers and magnets were now largely at an end.

In Nottingham my magic angle spinning research continued with Jim Carolan and Waldo Hinshaw and also my interest in molecular dynamics in solids, where I became fascinated with a new form of dynamic behavior, conformational motion.^{27,28} In materials such as solid cyclobutane, rapid inter-conversion of conformers leads to NMR line narrowing and relaxation; at higher temperatures it can lead to conformational order–disorder and a specific heat anomaly. Conformational disorder is propagated in a manner analogous to spin waves

and the quasiparticle characterizing elementary excitation of conformational waves I called a conformon (1971). I suppose we would all like to discover a new elementary particle and if not a 'real' particle, then at least a quasiparticle. After all, a quasiparticle is not only the next best thing to a real particle, it is just about as fundamental as some real particles!

I had earlier been interested in the NMR of simple solid compounds of biological interest such as urea and the polymethylammonium ions. From 1970 onwards this became one of my more positive interests and we began to examine a wider group of compounds important in biology. We started with proton NMR relaxation investigations into the solid state of the whole family of 20 amino acids from which proteins are assembled.^{29,30,31} We identified or confirmed their molecular form and determined the molecular dynamics of methyl, amino, and other groups. In this work I was fortunate to have the collaboration of Waldo Hinshaw, Michael Hutchins, and Rolf Sjöblom. For Rolf the year in my laboratory was part of his doctorate work for the University of Uppsala in Sweden. It led to my going to Uppsala the following year as his official 'opponent' at the public doctoral examination in the presence of his department, family, and friends and reminded me of the old medieval disputations.

From amino acids we moved on to the NMR relaxation study of polycrystalline dipeptides, tripeptides, and homopolypeptides. We were now poised to examine solid proteins³² by NMR. The advantage of relaxation investigations in the solid state is that large molecules are rather immobile and one is therefore studying directly the intramolecular motions of groups and segments. In solution such motions are superimposed on the motion of the molecule as a whole and in analyzing the relaxation behavior it is difficult to disentangle the internal motions in a clear and unique manner. David Bryant and Eamonn Cashell joined me in examining lysozyme,³³ ribonuclease,³⁴ α -chymotrypsin,³³ and insulin,³⁵ three enzymes and a hormone. Using the knowledge gained from the precursors we could identify motions attributed to segmental motion, to methyl groups and side chains, to proline conformational motion, and to the motion of water molecules intrinsic to the structure.³⁶ Dr. Gaspar visited us from Hungary and by studying $T_{1\rho}$ and T_{1D} we were also able to investigate very slow molecular motions.³⁷ A year's visit by Professor Michael Hoch from Johannesburg in South Africa provided the opportunity also to investigate the proton dynamics in DNA and its component bases³⁸ in the solid state.

In 1979 changes in China brought our first visitors from that country for many years and were delighted to welcome Mr. Quin-An Meng from the Institute of Physics in Beijing, who came to work with us for two years. He contributed to our work on insulin and other proteins and also polypyrrolone. He later arranged for me to visit well-equipped NMR centers in China at Beijing, Shanghai, Wuhan, and Fuzhou.

While all this work was going on a new chapter in NMR suddenly opened. Waldo Hinshaw, Bill Moore, and I attended the ISMAR meeting in Bombay in January 1974, where we heard Paul Lauterbur talk about NMR imaging, which he called Zeugmatography.³⁹ Waldo and Bill soon devised an alternative approach and on our return to Nottingham, Waldo, working in my laboratory with our Bruker spectrometer, was producing NMR images in a few weeks⁴⁰ and was able to present some very good images of small objects including a spring onion at the Nottingham AMPERE Congress in

September 1974. The future potential of this technique in biology and medicine was clear, and Bill and I obtained a grant from the Medical Research Council to pursue NMR imaging on objects of larger size. Here was a procedure capable of giving excellent images of the interior of the body without the use of ionizing radiation. Waldo returned from America to rejoin the project and we were also joined by Neil Holland and an Australian research student, Paul Bottomley, who went on to make a name for himself in the subject in the United States.

With a magnet having a 13-cm aperture, good, geometrically faithful images were obtained in 1977 of a lemon and other fruit, and of the abdominal anatomy of a rat. We also obtained the first NMR images of a human hand,⁴¹ wrist,⁴² and forearm. The image of the lemon appeared on the front cover of *Nature* in 1977. The question then arose whether the radiofrequency fields needed for NMR would adequately penetrate human tissue for imaging the whole head and body. Paul Bottomley and I carried out a calculation⁴³ assuming a simple cylindrical model of the body and concluded that penetration would be almost complete at the frequencies to be used. It was a great pleasure to us that this paper, which was frequently quoted, became a Citation Classic. Then with support from the Wolfson Foundation a whole body NMR imaging system was constructed which gave images of the human head and body, both normal and diseased,^{44,45} with the first clinical assessment of pathology. By now we needed clinical advice and we were fortunate to have the active interest and collaboration of Dr. Brian Worthington, Professor of Diagnostic Radiology at Nottingham University Medical School. Meanwhile a very successful parallel series of investigations was being carried out in the Department of Physics by Professor Peter Mansfield and his colleagues using somewhat different techniques.⁴⁶ Our early NMR images played a part in convincing medical instrument manufacturers to produce commercial NMR scanners, nowadays a huge industry, and it led to our becoming consultants first with EMI and then with GEC, working with Dr. Hugh Clow and Dr. Ian Young, who obtained the first human head images.⁴⁷

Physicists are great conference people and love to get together and discuss their work with others in their field. In April 1976, we organized the first international conference on NMR imaging in Nottingham. Most of the activists in the world of magnetic resonance imaging of the day, about 25 in all, were there.

BRSO continued to provide magnetic resonance meetings at the national level in Britain and the Groupement AMPERE at the European level. It was Professor René Freymann of France who suggested that AMPERE's name provided an appropriate acronym: Atomes et Molécules Par Etudes Radio-Électriques, and we therefore often write it out in capital letters. The AMPERE Group originally catered for French speakers but as its popularity grew, papers in English were allowed and eventually English took over as the primary language. AMPERE Congresses, Colloques and Summer Schools were held in most European countries from Lisbon in the west to beyond the Urals in Novosibirsk and Shushenskoe in the east, from Turku in the north to Crete in the south. It provided an excellent vehicle for meeting magnetic resonance scientists in Europe despite the political divisions of those days. After organizing the 18th AMPERE Congress in Nottingham in 1974, I had the honor of being elected President of the

Groupelement AMPERE and served till 1980. The Groupelement AMPERE owes much to the dedicated service of its Secretary-General, Georges Béné, who served for 34 years till 1990. He is a wonderful person and a great friend. In 1994 the AMPERE congress went to Kazan to celebrate the discovery of ESR by Zavoisky²⁶ there 50 years ago. Besides these activities in Europe there was a need for worldwide meetings of magnetic resonance scientists and in 1971 at a meeting in Israel, the International Society of Magnetic Resonance (ISMAR) was founded, spearheaded by Professor Daniel Fiat, who was its Chairman till 1983. A new constitution was agreed in that year with a rotation of officers, and I served as the first President of ISMAR till 1986. In 1995 ISMAR will hold its triennial meeting in Sydney, Australia, and will celebrate the discovery of NMR 50 years earlier.

The years were passing and I began to notice without enthusiasm that the age of my compulsory retirement (65) at Nottingham University was approaching. So I was very delighted to receive an invitation to come to the University of Florida in 1983 as a Research Professor, without a specified date of retirement, and I accepted with great pleasure. Here in Florida I have joint appointments in the Physics Department and in the University Medical School, and I spend half my time in each. I had earlier spent a year of sabbatical leave working in Florida with my old friend, the late Tom Scott, whom I knew from Harvard days, and I am particularly grateful to old colleagues from that year, especially Jim Brookeman and Kate Scott, for this opportunity. Here the winters are warm, I have palm trees outside my office window, and we never have snow or ice or fog. I encourage my friends from cold places to visit us!

In the Physics Department I have been able to continue my NMR research on molecular solids. A long-standing exchange program with Poznan University in Poland has provided a series of excellent postdoctoral fellows from the laboratory of Professor Pajak. We have investigated molecular structure and dynamics in solid carbohydrates, sugars, cholesterol,⁴⁸ cortisone, progesterone, testosterone,⁴⁹ lactic acid and lactates, *t*-butylselenol,⁵⁰ AMP, ADP, and ATP. However, it has been remarked that life is lived in aqueous solution and with this in mind we have also investigated relaxation and relaxation mechanisms in these and other metabolites in aqueous solution for ¹H and ³¹P using high-resolution NMR spectrometers in a renewed collaboration with Professor Gaspar from Hungary.^{51,52} This knowledge is very useful in MRS investigations of quantitation, NOE, saturation transfer, dynamics, and exchange.

Shortly after my arrival in 1983, the University of Florida hospital acquired one of the first generation commercial 0.15 T whole body NMR imaging systems. It was manufactured by Technicare where Dr. Waldo Hinshaw was in charge of NMR technology. It served us well for several years and Technicare gave us a second system dedicated to research. These years witnessed a rapid development of MRI to become a regular clinical modality of radiological investigation and the method of choice for many disease situations. With the advances in superconducting technology we replaced these early systems and currently we have two 1.5 T systems and a 3 T system. So the University of Florida has extremely good NMR imaging facilities devoted primarily to patient care, but also providing excellent opportunities for MRI and MRS research.⁵³ We also have a 4.7 T 33-cm bore NMR imaging spectrometer for

smaller scale and animal research, together with 7 T and 14 T high-resolution spectrometers suitable for NMR microscopic imaging. Besides taking advantage of these facilities, I have also been making contributions to magnet screening^{54,55} and to novel field gradient systems.

I was glad to find I had not been totally forgotten in my home country when in 1984, I was elected to Fellowship of the Royal Society, the citation specifically mentioning contributions to NMR. Shortly afterwards I shared the Royal Society's Wellcome Medal and Prize with Jim Hutchison, John Mallard, and Peter Mansfield for our contributions to NMR imaging. We have happily stayed in the United States, continuing to work, but returning to Britain frequently. I was especially glad to be welcomed back to Nottingham in 1992 to a BRSg meeting held in honor of my 70th year. From Florida I was able to take sabbatical leave back to England in 1989, spending it in Cambridge as a Fellow of Christ's College, where I had been an undergraduate 50 years earlier, and I worked in Professor Laurie Hall's new NMR laboratory in the University Medical School, where MRI and NMR microimaging are a specialty.

In Florida a new horizon opened when I was asked to start the new journal *Magnetic Resonance in Medicine* as Editor-in-Chief. The journal was urgently needed in this burgeoning field and grew rapidly, reaching the top of the impact table in its group of 50 radiology journals. After 8 years, I retired from the editorship in 1991, and the Society of Magnetic Resonance in Medicine most kindly awarded me their Distinguished Service Medal.

The most recent magnetic resonance excitement in Florida comes from the new US National High Magnetic Field Laboratory created in Florida under grants from the National Science Foundation and the State of Florida. Begun in 1991, it is now complete and open for business. NMR at the highest magnetic fields is one of the many areas of science to be undertaken at the laboratory, along with ESR and ICR. Centered in Tallahassee, the NHMFL has outposts in Los Alamos and in Gainesville, and several of us at the University of Florida serve on the NHMFL planning committee and are active in prosecuting this exciting new venture.

Finally, I would like to say what a tremendous privilege it has been to work in this great subject of nuclear magnetic resonance for close on 50 years. It has been an inspiration to participate in this adventure over the years with many able colleagues including some 30 postdoctoral fellows and 40 graduate students, and I am most grateful to the pioneers of NMR who made this possible. The subject is still very active with new developments opening up continually. We can be confident of a very bright future for NMR.

Biographical Sketch

E. Raymond Andrew. b. 1921. B.A. (Physics), M.A., Ph.D., Sc.D., Cambridge University, UK, Hon. D.Sc. Turku, Poznan, Leipzig, FRSE and FRS. Postdoctoral fellow, Harvard with E. M. Purcell. Lecturer, St. Andrews University, Scotland. Professor of Physics, University of Wales, Bangor. Professor and Dean of Science, Nottingham University, England. Currently Research Professor, University of Florida, USA. President, Groupement AMPERE, 1974–80. President, ISMAR, 1983–86. Editor, *Magnetic Resonance in Medicine*, 1983–91. Four books: *Nuclear Magnetic Resonance*, *Magnetic Resonance and Related Phenomena* (jtly), *Clinical Magnetic Resonance* (jtly), *NMR in High Magnetic Fields* (jtly), 325 publications. Research interests: NMR in condensed matter, NMR imaging, MR in medicine.

Anet, Frank A. L.: A Lapsed Organic Chemist in the Wonderland of NMR

Frank A. L. Anet

University of California, Los Angeles, CA, USA

INTRODUCTION

I first heard about NMR in 1954 when I was a postdoctoral fellow in a natural products laboratory headed by Léo Marion at the NRC (National Research Council of Canada) in Ottawa. Close by was H. J. Bernstein's Raman spectroscopy laboratory. Communication between these two research groups on the social level was greatly helped by occasional evening bridge games. The organic chemists thus learned that H. J. Bernstein and W. G. Schneider were getting expensive instrumentation to do a new kind of spectroscopy. I remember well the talk amongst the postdoctoral fellows: what were the odds that this spectrometer would turn out to be a white elephant because applications to chemistry would prove to be limited and fleeting? No one, of course, knew the answer to this question or remotely guessed the revolutionary influence that NMR would have on so many areas of science (including organic chemistry). In this contribution I describe especially how I entered the field of NMR and my early research in this area. My interests gradually shifted from natural product chemistry to physical organic chemistry and conformational analysis by means of dynamic NMR, to instrumentation and relaxation aspects of NMR. All along I maintained a strong connection with my organic chemistry colleagues.

UNIVERSITY OF OTTAWA

In September 1954 I joined the fledgling bilingual University of Ottawa. Ray Lemieux was the Chairman of the new Department of Chemistry and was most helpful to my career, not least because he himself got involved in NMR (with his student Rudy Kullnig) in collaboration with the group at the NRC at a very early date.

As a result of intense efforts by Ray Lemieux, a 60 MHz NMR spectrometer was funded by the NRC and installed in early 1959 at the University of Ottawa. At the time, few universities had NMR spectrometers, and even fewer organic chemists had good access to an NMR spectrometer (J. D. Roberts at Caltech was a prominent exception). I was very lucky indeed.

I had become interested in obtaining NMR spectra on a new alkaloid even before the University of Ottawa had acquired its own 60 MHz NMR spectrometer. Harold Bernstein at the NRC ran a 40 MHz spectrum of an alkaloid that we knew contained a pyridine ring from its UV absorption, and the NMR spectrum immediately (and correctly) told us that it was a 2,3-disubstituted pyridine. From an unsplit methyl peak signal in the spectrum we concluded (incorrectly, as we

showed later) that a methyl group was bonded to a quaternary carbon. We published these results in 1958 in my 20th paper¹ (and the first one to include NMR data); a reference to this paper found its way into Pople, Schneider, and Bernstein's classic book² on NMR, published in 1959. The appearance of an unsplit methyl signal in a CH₃–CH moiety, where the chemical shift difference was large compared to the vicinal coupling constant, expected to be about 7 Hz, subsequently impressed on me the importance of NMR spectral analysis. When I understood what was going on, I wrote a paper³ which was published in 1961 on the nature of the signals of C-methyl groups, and this explained many anomalous 'coupling constants' involving methyl groups in steroids and other compounds; it anticipated later research by others on virtual coupling. Although spectral analysis is becoming almost a lost art in the midst of so-called 'modern NMR', it is in fact just as useful and necessary as it has ever been, in my own experience.

My interest in reaction mechanisms led me to study the spectra of the isomeric 2,3-dibromobutanes and this work,⁴ published in 1959, also foreshadowed an important concept in the understanding and analysis of complex spectra, namely subspectrum analysis. Here again methyl signals that I had (naively) expected to be doublets instead showed six lines; a full paper was published in 1962.⁵

Work on the configuration of enzymatically produced deuterio-L-malic acid, the use of remote deuteration in spectral analysis, and the determination of the negative sign of the geminal coupling constant in CH₂DOH were published^{6–8} in 1960–1962 and all involved deuterated compounds. The latter work employed a special irradiation scheme because the standard decoupling methods for relative sign determination were not applicable. I used the decoupling theory published by Bloom and Shoolery;⁹ I was of course not aware of the extensive investigation on 'spin tickling' done by Anderson and Freeman¹⁰ and submitted and published at almost exactly the same time as my article; as it turns out, I had unwittingly spin tickled CH₂DOH! The frequency stability of the decoupler (made by NMR Specialties) was actually too poor for spin tickling, but I found a simple way to stabilize it. This was my first venture into NMR hardware and I was so encouraged by its success that, despite knowing very little electronics, I later decided to build a whole spectrometer!

The use of deuterium to simplify spectra and later to investigate isotope effects on chemical shifts has been a recurring theme in my work. Other continuing topics have been conformational investigations of ring systems, restricted rotation, and atom inversion, and here also deuterium substitution combined with dynamic NMR has been vital. My first encounter with dynamic NMR was accidental and I did not immediately recognize it. In 1959, I measured the spectrum of an alkaloid, strychnospermene, which I had related chemically to strychnine as a part of my Ph.D. work with Sir Robert Robinson at Oxford University. The coalescence temperature for one of the protons at 60 MHz was close to room temperature and the signal was so broad as to be invisible (the alkaloid is an *N*-acetylindoline derivative); all the other signals were sharp. Our probe initially did not allow the temperature to be varied, and thus I did not realize what was happening until several years later.¹¹

The importance of magnetic equivalence and nonequivalence and my interest in spectral analysis forced me to learn some group theory and to make use of quantum mechanics; I

developed a strong interest in symmetry properties which ultimately extended well beyond NMR. The breaking of symmetry in a molecule by isotopic substitution particularly fascinated me. For example, the boat-shaped 1,3,5,7-cyclooctatetraene in solution gives only a single line in its proton spectrum at all temperatures, even though the molecule has two different vicinal coupling constants. The bond shift process that exchanges the double bonds with the single bonds does not affect the spectrum. The ^{13}C satellites of this line show a dynamic NMR effect at about -10°C , allowing the barrier to the bond-shift process to be measured. This, by the way, was a predicted encounter with dynamic NMR, a technique that fitted ideally with my aspiring physical organic interests. I promptly submitted a communication on the cyclooctatetraene work to the *Journal of the American Chemical Society* and soon received a signed referee report from Jack Roberts at Caltech. He informed me that he and his student, George Whitesides, had made similar observations, so it was fortunate that I had not delayed submitting a paper. It was published in 1962¹² with a mention of Roberts and Whitesides's work.

UNIVERSITY OF CALIFORNIA, LOS ANGELES

In 1962, I received a phone call from Saul Winstein asking me whether I would like to come to UCLA as a visiting professor for one semester and teach a graduate course in physical organic chemistry. I accepted and my wife and I spent the first half of 1963 in Los Angeles, where the winter temperatures are more like those in Sydney, where I had done my undergraduate work, than in Ottawa. This initial contact led to my joining UCLA in the summer of 1964.

At UCLA, my students and I used a 60 MHz Varian spectrometer with a 12-in. magnet and an internal lock and frequency sweep system that I had built in Ottawa and brought with me. Other organic chemistry students used the convenient new Varian A-60 spectrometer, which however lacked the decoupling and very low-temperature capability that we had added to the older spectrometer. A little later we also used a Varian HA-100 spectrometer that the department acquired.

The years 1963 and 1964, spent partly in Los Angeles and Ottawa, were quite productive on both the organic chemistry and NMR fronts. Ring processes in 1,3,5-cycloheptatriene,¹³ deuterated cyclooctane¹⁴ and cyclohexene,¹⁵ restricted rotation in benzaldehyde,¹⁶ and nitrogen inversion in aziridines¹⁷ started a lasting interest in low-barrier dynamic NMR processes. We also used NMR extensively in our research on alkaloids,¹⁸ to detect some unusually stable hydrogen-bonded dimers,¹⁹ and in the first synthesis of a benzocyclopropene derivative.²⁰

Tony Bourn, a postdoctoral student from Randall's laboratory, who had helped elucidate in Ottawa the ring-inversion and bond-shift processes in derivatives of cyclooctatetraene,²¹ came with me to UCLA. He carried out a careful study of the ring inversion in cyclohexane- d_{11} ,²² following earlier preliminary work.²³ Tony was also involved in a very important paper, the first use of the proton-proton NOE for structural purposes.²⁴ We were trying to detect a possible but undoubtedly small and unresolved coupling between two strongly sterically compressed protons. We irradiated one of the signals and immediately noticed that the height of the other signal had increased, but when we tried to measure the expected

decrease in linewidth, we found that there was none! Clearly the area of the peak had increased. We then found that we could get a similar behavior in *N,N*-dimethylformamide, but only when the methyl group *cis* to the formyl proton was saturated. This kindled my interest in relaxation and resulted in many hours over the years spent with Abragam's book. While on the subject of relaxation, I might mention a short stay in 1971 at the General Electric Company visiting George Levy and working on ^{13}C relaxation problems.²⁵ Much later (1989) I spent a short time, together with my student Dan O'Leary, with Chuck Wade and Bob Johnson at the IBM laboratories in Almadén, where we found a ^{13}C resonance having a T_2 longer than T_1 .²⁶ During the late 1980s, the extraordinary relaxation properties of aromatic protons in viscoelastic micellar solutions were elucidated.^{27,28}

Work at UCLA in the 10 years after I joined, some in collaboration with Chris Foote, Don Cram, Herb Kaesz, and Saul Winstein, was highly productive and was initially done on 60 and 100 MHz spectrometers. Maurice St.-Jacques, Mark Henrichs, Jim Sudmeier, Mary Brown, Jan Sandström, Geo Schenck, Larry Bock, Linda Sweeting, Duncan Mullis, Maurice Brookhart, François Leyendecker, and O. Abrams participated in this research, which is too extensive and varied to discuss here.

By 1964, Varian Associates had demonstrated the usefulness of superconducting solenoids for NMR and had built a 200-MHz prototype NMR spectrometer for DuPont. I applied to NIH for a grant to buy a superconducting solenoid from Varian and to build the rest of the (sweep) spectrometer myself. After some time the grant was funded, but then Varian announced they were stopping the production of solenoids until they had solved severe problems with unexpected quenching. After about six months Varian decided that they would only produce complete 220 MHz spectrometers, and not individual solenoids. I ultimately ordered a solenoid from Magnion, a company with no experience in NMR. Because of the delay, new niobium-titanium wire with a large amount of copper for stabilization had become commercially available and was far better behaved than the niobium-zirconium wire with only a thin copper coating that had to be used earlier by Varian. Another fortunate accident was that Magnion decided to make a solenoid with a bigger bore than Varian was using.

I built a very simple spectrometer from a 70 MHz frequency synthesizer and pulse generator (both from General Radio) and some Hewlett Packard double-balanced mixers for time sharing rf switches and phase detectors. Gwen Chmurny worked with me trying to find deuterium resonance at 38.4 MHz, which was hampered by the field homogeneity being a factor of 10 worse than the specification, and by the solenoid being far from persistent. We returned the solenoid to Magnion a couple of times, waited several months each time, but never received a satisfactory product.

Ned Baker at Dow Chemicals had also ordered the same kind of solenoid as we had from Magnion and was helpful to us. The welded superconducting joints made by Magnion were not persistent and were remade by Craig Bradley with a cold-welding machine lent to us by Ned. Craig built most of the spectrometer. We published our first two papers^{29,30} on dynamic NMR processes that could only be poorly or not observed at lower frequencies while the spectrometer was still under construction. Craig's thesis,³¹ which was submitted in early 1970 just before he joined Bruker, was on NMR

instrumentation (plus a few applications); he had originally wanted to work with me on natural products, a field that I decided not to pursue once at UCLA.

Another person who was helpful to us, especially in shim coil design, was Joe Dadok at Carnegie-Mellon. We soon added ^{13}C and ^{11}B capabilities to our spectrometer, which operated at 59 kG (5.9 T, 251 MHz proton frequency) in a time-shared frequency sweep mode. We managed to acquire a Data General Nova computer with 24 kbytes of memory, an ASR 33 teletypewriter, and a fast paper tape reader. Tony Cheng and I programmed the Nova in assembler language and Vladimir Basus built A/D and D/A interfaces to the spectrometer, to which a pulse capability was added. A little later we thankfully acquired a hard disk and more memory. Of course, in only a few years the hardware was almost obsolete, something that has not changed to this day.

Using the 251 MHz spectrometer, we determined the conformational properties of a large number of molecules, mostly by dynamic NMR in association with molecular mechanics calculations, and we did isotope effects and relaxation studies. The persons doing this work were: Tony Cheng, Vladimir Basus, Roy Easton, Lech Kozerski, Peter Degen, Jostein Krane, Gerald Buchanan, Armand Dekmezian, Issa Yavari, Mehran Ghiaci, Tarik Rowdah, Joseph Wagner, and Mike Squillacote.

I do not have space to recount here Jane Strouse's work with matrix shim coils or the design and winding of an Nb–Ti superconducting solenoid. A proton frequency greater than 400 MHz was reached, although we chose to operate the spectrometer at 396 MHz. We described our efforts at several ENC meetings in the late 1970s. This spectrometer was used in the next few years by myself, Dan Donovan, and Brad Bacon and regularly (once a week) by Fred Hawthorne's students at UCLA to obtain ^{11}B spectra of carboranes.

The departmental NMR facility at UCLA, which was then under the direction of Jane Strouse, had been using a JEOL FX-90Q and a Bruker WP-200 spectrometer for several years to which it added a Bruker AM-500 MHz spectrometer in 1984. These instruments were used by Xia-Hui Ji, Kaozheng Li, Zhihong Tan, and Jaemin Park in a variety of NMR projects. Max Kopelevich synthesized a chiral compound containing a $-\text{CH}_2\text{D}$ group where the two diastereotopic protons have observably different chemical shifts.³² If the $-\text{CH}_2\text{D}$ group is replaced by a $-\text{CHDT}$ group, the two diastereomers that result have observably different ^3H chemical shifts, which were assigned in work done by Dan O'Leary in collaboration with Heinz Floss and co-workers at the University of Washington.³³ In our most recent work, done in collaboration with Martin Saunders and co-workers at Yale University, Darón Freedberg obtained ^3He NMR spectra of ^3He encapsulated inside the fullerenes C_{60} and C_{70} .³⁴

I have mentioned in the text or references nearly all the persons who worked with me on NMR at the University of Ottawa or at UCLA; recent outside collaborators whose names I have not mentioned yet are: George Olah and Surya Prakash (University of Southern California), Kurt Mislow (Princeton), Jay Siegel (UCSD), Leo Paquette (Ohio State University), and Phil Williams (UCB). Thanks are due to all of them, to the granting agencies that supported our work, and to my

predecessors and contemporaries in NMR for making NMR a wonderland for me.

Postdoctoral work at Oxford and the National Research Council of Canada, Ottawa. University of Ottawa, Ontario, Canada, 1954–64; University of California, Los Angeles, CA., 1964–present. Emeritus Professor of Chemistry. Approx. 220 publications. Research interests

include conformations of organic molecules, dynamic NMR, molecular mechanics, isotope effects in NMR, relaxation phenomena, NMR instrumentation, and helium-3 NMR of fullerene–helium compounds.

Arata, Yoji: Early Days of NMR in Japan

Yoji Arata

University of Tokyo, Hongo, Tokyo, Japan 113

In 1959, when I became interested in NMR as a graduate student majoring in organic chemistry, only a few NMR instruments had been installed throughout the whole of Japan. Using a low magnetic field strength which gave the proton resonance at 56.44 Mc/s on a Varian instrument then in operation at the Japan Atomic Energy Research Institute, I had difficulties in analyzing the three-spin proton spectrum of acrylic acid which had been measured with the help of Ichiro Yamaguchi and Naohiro Hayakawa at the Institute. I had to face a number of difficulties in the spectral analysis. The first was the problem of a severe signal overlap encountered at the low magnetic field which was eventually overcome by making use of the solvent effect of benzene. This was followed by the more difficult problem of the spectral analysis of the strongly coupled three-spin system. Hiroshi Shimizu, who was a research associate in Professor Shizuo Fujiwara's laboratory at the University of Tokyo, and I developed a least-squares method for the spectral analysis of strongly coupled spin systems. However, at that time, numerical calculations could only be done using a hand calculator available from the Tiger Computer Company. I had to spend at least a week, if I was lucky, to reach a converged solution.

However, in 1961 the first digital computer in Japan became available to us. This was the Parametron PC-1 computer built by Professor Hidetosi Takahasi and his graduate student Eiichi Goto at the Physics Department of the University of Tokyo. Although the computer memory was only 256 words, one word being 24 bits, this was sufficient to allow a tremendous speeding up of the calculation. In most cases, one overnight calculation was sufficient to reach the refined sets of parameters for the three-spin system.

The calculation became even faster when Hidetosi Takahasi's group built their second computer PC-2 with 1024 words. With the help of Takao Iijima and Isao Suzuki, who were then at the Department of Chemistry, University of Tokyo, I was able to write a program in machine language for PC-2 for spectral analyses of the proton spectra of strongly coupled spin systems. I used the program for the analyses of the spectra of amino acids and published a series of papers in the *Bulletin of the Chemical Society of Japan* and the *Journal of Molecular Spectroscopy*. By that time Masatami Takeda and Oleg Jardetzky had already published a report on their successful attempt to use NMR for conformational analyses of some of the amino acids. This experience eventually led me to join Oleg Jardetzky's group at Stanford in 1971, where I started a proton NMR study of proteins. Since then I have spent more than 20 years engaging in multinuclear magnetic resonance molecular structural analyses of antibodies.¹

Based on my experiences since the early days of my NMR career, I should like to make the following comments. One is related to the algorithm of fast Fourier transformation (FFT). The development of the FFT algorithm has a long and interesting history. The FFT algorithm dates back to

1903, when Runge exploited symmetry and periodicity to simplify the numerical calculation of Fourier transformation. In 1965, Cooley and Tukey published their well-known paper describing the FFT algorithm. Although the names of those associated with the history of FFT have been recorded, probably one exception only is that of Hidetosi Takahasi.

Many of us in the Japanese scientific community involved in numerical calculations using Fourier transformation know that Hidetosi Takahasi deposited his own FFT program in the library of the computer center at the University of Tokyo. Everyone who knows him well agrees that Hidetosi Takahasi is a virtuoso in physics. However, for those with the background of Western civilization he might appear an enigmatic person. He was not at all interested in what was going on outside his office, and in most cases was not interested in publishing what came to his mind either; it was his belief that physicists had to create everything on their own initiative. Toshiko Tochigi, a former associate of his, recalled that Hidetosi Takahasi was a quiet man who talked very little about what was in his mind. He showed her once his program for the computation of a Fourier transformation, and made some suggestions about the revision of his program. According to the record left in the computer center at the University of Tokyo, the final version of Hidetosi Takahasi's program was deposited on August 23, 1966. It is not my intention at all to claim that Hidetosi Takahasi was the first man in the world to have developed the FFT algorithm, but I should simply like to stress that as early as the mid-1960s an FFT program was being used successfully in Japan, independently of what was going on in the rest of the world.

Second, I should like to comment on the theoretical analysis of the effect of anisotropic Brownian motion of molecules on their nuclear relaxation. In virtually all papers published outside Japan, the work of D. E. Woessner is cited as the first report on this subject. This paper was published in the August 1, 1962 issue of the *Journal of Chemical Physics*. Very little, however, is mentioned even in Japan about Hiroshi Shimizu, who published his independent analysis of the effect of anisotropic Brownian motion in the August 15, 1962 issue of the same journal. My concern is that Shimizu's manuscript was received in the office of the Journal on June 6, 1961 and was printed more than one year later, whereas Woessner's manuscript was received on April 25, 1962. In addition to this important work, Hiroshi Shimizu has made a tremendous contribution to the theoretical analyses of nuclear magnetic relaxation; most of his work is summarized in his Ph.D. thesis (University of Tokyo, 1961). Unfortunately, before the dawn of FT NMR, experimental NMR techniques were at a very primitive stage and it was virtually impossible for Hiroshi Shimizu to perform any experimental study to follow what he had predicted on the basis of his theory. He left NMR soon after he finished his Ph.D. work and became interested in the theoretical treatment of irreversible processes in a more general sense. He is now the Director of The 'Ba' Research Institute, Kanazawa Institute of Technology and International Media Research Foundation, and has published a series of interesting pieces of work relating to the theory associated with analyses of irreversible processes in biological systems.

Before closing my brief recollections of the early days of NMR in Japan, I should like to mention the name of Kazuo Tori, who to our great shock passed away in 1982 at the age of 51 when he was Research Director, Division of NMR

Spectroscopy, at Shionogi Research Laboratories, Shionogi & Co., Ltd. His contribution to the development in Japan of the use of NMR in the field of organic chemistry was phenomenal. It is unfortunate that his days coincided with those of CW 100 Mc/s one-dimensional NMR. In view of his scientific achievements which amounted to more than 230 papers, I am certain that with modern multidimensional techniques he would have made a tremendous contribution to exploring the fascinating world of NMR in the field of organic chemistry.

This brief note is dedicated to the memory of the late Dr. Kazuo Tori. I thank Dr. Yoko Takayama, Shionogi & Co., Ltd. for giving me a chance to talk to her and recall the days when we both enjoyed discussions with Dr. Kazuo Tori. I also thank Dr. Hiroshi Ozawa and Toshiko Tochigi, Computer Center, University of Tokyo, and Professor Toshiyasu Kunii, Aizu University, for discussing the scientific achievements of the late Professor Hidetosi Takahashi. Discussions with Professor Masatsune Kainosho, Tokyo Metropolitan University, have always been encouraging and stimulating in continuing my NMR career.

Arnold, James T.: Early Perceptions in Nuclear Magnetic Resonance (NMR)

James T. Arnold

P.O. Box 314, Los Altos, CA, USA

The purpose of these paragraphs is to try to recreate some of the atmosphere and the views and perceptions of the early days of NMR as I saw them. My point of view was that of a callow graduate student at Stanford University, a novice confronting other far more experienced graduate students and the very accomplished faculty of the Stanford University Physics Department. Standout names in the faculty included Paul Kirkpatrick (X-Rays), David Webster (Electromagnetism), Leonard Schiff (Theoretical Physics and Quantum Mechanics), William Hansen (Microwaves and NMR), Willis Lamb (Quantum Electrodynamics), and Felix Bloch (Theoretical Physics and NMR). The stature of these professors has been recognized in a notable array of distinctions, including two Nobel Prizes. It was my good fortune to be on the scene when there was room for another candidate in the NMR cadre. The first student to complete his NMR thesis, Martin Packard, was retained as a first year instructor, and I was attracted to his continuing work with Bloch. I was introduced to the NMR activity through low level screwdriver and soldering iron contributions to Packard's project at the time, and happily found myself accepted as a member of the NMR team when Professor Bloch gave me a most friendly and graceful interview.

There was no way to know at the time the extent to which application of NMR would expand to become a very productive contributor to the scientific community and to mankind. NMR was first an investigative method for physicists, delivering at the first instance a table of nuclear moments. It then became, second, a major means to elucidate molecular structures for chemists. Still later, it has come to furnish a powerful diagnostic tool for medicine, providing noninvasive tomographic imaging with views and contrast not previously available to X-ray shadow viewing or tomography.

The progress of NMR has also produced important advances in collateral technology. First, the art of producing very high magnetic fields of ultrahigh quality has been advanced beyond the most visionary expectations, beginning by pushing the advantage of iron as far as saturation properties permitted, and then progressing to an ascending series of cryogenic superconducting magnets.

Second, signal levels in NMR are painfully small, and from the beginning, it was necessary to improve the 'receiver' element's noise figure and other qualities as far as Nature would permit. To access the information content of the NMR signal requires acquisition of low level closely spaced radiofrequency spectral components. Stability of electronics was a crucial contributor to acquiring signals through integration over longer and longer periods of time.

Quite apart from the integrating time, extended to improve signal-to-noise in order to capture these spectral signals, the time required to sweep through each spectral component

scanned necessarily increases as the reciprocal square of the fineness of the lines as resolution is improved. This condition grows out of the fact that the nuclei interrogated are gyrators whose motion continues after excitation, with substantial memory of the interrogation event. Probing the spectrum requires a time period to wait for that motion to relax for each spectral line passed, and this puts severe demands on the stability of the excitation frequency and the magnetic field that they remain stable during an experiment to a scale much finer even than parts per million. To help solve this problem, at a later date, a remarkable shortcut to acquire signals from all the spectral components simultaneously, superposed in the time domain, was brought to bear. The spectral information was present, albeit in an unfamiliar form as the Fourier transform of the familiar spectra in the frequency domain. This method was originally suggested by Russell Varian, long before the computation problems could be addressed with machines of sufficient power and speed. When it became possible with the development of better computers and electronics, the Fourier transform process produced useful analysis at a dramatically increased rate, and the development of transform methods under the demands of NMR has provided benefits in other areas of scientific application.

Figure 1 First record of chemical shift structure in proton NMR spectra. (a) Acetic acid; (b) ethyl alcohol (Reproduced by permission from *Journal of Chemical Physics*, 1951, **19**, 1608)

Looking back to the earlier days, I have been struck by the extent of progress and understanding achieved with relatively simple hardware, and with good fortune, as to some physical constants in the chemical aspects of NMR spectroscopy. Before my thesis was assigned, I participated with Packard and Dr. Shrinivas S. Dharmatti, a postdoctoral investigator visiting Stanford from the Tata Institute in India, in an experiment that demonstrated two separate chemical shifts of protons in the same molecule (acetic acid), see Figure 1. Credit for suggesting that an NMR ‘spectrum’ arising from distinguishable protons in a single molecule could be observed belongs to Dharmatti. The delicate separation of the chemically shifted lines is field dependent and amounts to just a few parts per million. It was only with very small samples and much empirical searching in the magnet for a ‘homogeneous spot’ that the separation of the spectral lines could be observed.

From acetic acid, we graduated almost immediately to ethyl alcohol (ethanol) and other alcohols as sample, observing in ethanol a gratifying set of three spectral lines corresponding to the three separate chemical groups, methyl, methylene, and hydroxyl that chemists describe to make up the structure of this molecule. The outcome of these experiments led to a publication in (appropriately enough) the *Journal of Chemical Physics*, (1951, **19**, 507). That publication was the springboard that propelled NMR into the world of organic chemistry, elucidating chemical structures by interpreting their proton NMR spectra. The NMR spectrum for ethanol, resolved as to the chemical shift, is also shown in Figure 1.

The magnet used for the experiment was a 12-in. electromagnet designed by Harry E. Weaver. The magnet produced a field of 7000 G (0.7 T), in a magnet gap of ca. 1.5 in. This field led to a proton resonance frequency of approximately 30 Mc/s. (I shall continue to use the names of units that were familiar to us at that time.) Although the poles were basically round with square edges, quasi Rose shims had been added to improve the homogeneity of the field in the center of the magnet. The difficulty of achieving a field of sufficient uniformity will be appreciated when one considers the fact that geometrical disturbances of the magnet pole caps must measure on a scale of parts per million multiplied by powers of the reciprocal ratio of the sample size to the gap width and the space wavelengths of the disturbances. In no way could the magnet parts be fabricated to the necessary precision, and much of the experimental effort was directed to discover the most favorable saddle points in the field. With luck, a sample of 1 mm diameter could be maneuvered to find a region with sufficient homogeneity to resolve the spectra sought.

I mentioned above the luck of some physical constants as they related to the spectra observed. First, the electron (diamagnetic) shielding that gives rise to the grosser spectral shifts of lines in the NMR spectrum (chemical shifts) is proportional to the magnetic field, and, in fields of a few thousand gauss, easily achieved in the laboratory, has a value significantly greater than the (then) apparent linewidths of the individual spectral components. Second, the time required at this stage of resolution to scan the spectrum was a few seconds or tens of seconds at most, and the magnetic field could be held with reasonable stability over this timescale. The luck that these two features fell into a range that could be reached with the experimental equipment achievable at that time evolved into a challenge to improve the apparatus further in order to probe deeper into the interactions that gave rise

to the spectra. We observed, first in the Weaver magnet, some evidence that there might be a finer structure, not yet resolved, in the spectrum of ethanol. When conditions were just right, we actually observed indications of further splitting of the chemically shifted lines seen up to that time. The challenge which became my thesis topic was to construct apparatus that had the stability and resolution to reveal that structure with useful precision.

Throughout this early exploratory period and in the progressive steps that followed, we, the cadre of graduate students in NMR, benefited from the welcome encouragement and intellectual support, and the intuitive insight of Felix Bloch. His scientific stature and contributions were recognized in the fall of 1952, when his award (with Edward M. Purcell) of the Nobel Prize was announced for the work in NMR.

It is also appropriate to acknowledge that financial support for the project and the graduate students was, in part, derived from grants from the Office of Naval Research (ONR) and the Atomic Energy Commission (AEC). This support was not in the grand scale of later government grants to academic institutions, and we were always looking for means to save money by building our own equipment and adapting items from the rich legacy of military surplus that became available following World War II. (Part of the reason for choosing the frequency of about 30 megacycles per second grew out of the fact that the intermediate frequency amplifiers of many WWII radars centered on this frequency. These very high quality amplifiers could be bought for pennies on the surplus market.)

In supplement to the financial support derived from the ONR, an anonymous grant of \$5000 was donated for use at Bloch’s discretion. He announced to me that if I could design a permanent magnet (that should be much more stable in the short term than the electromagnets used up to that time for NMR), the \$5000 fund was available to finance it. This was very exciting. After calculations and investigations we determined that if we chose available low-cost materials that could be handled in the Stanford Physics Department shop, we could construct a magnet of the sort we wanted within the budget available. The largest dollar investment would be to cover 18 bars of Alnico totaling about 1400 lb.

The detailed design of the magnet is described in an article in *Physical Review* (1956, **102**, 136); I will comment here on just a few features to emphasize the atmosphere in which the leading edge of physics often took place in the years just after WWII.

The frame of the magnet was constructed of yoke members each comprising 12 lamina of cold rolled steel (low carbon) 1 × 6 in. in section which could be manhandled in the shop and then bolted together. Planning of the project included a note that it would be necessary to magnetize the Alnico with a closed gap; it was therefore required to design the magnet with an adjustable gap, still maintaining considerable mechanical precision. The adjustable gap was provided by mounting one pole of the magnet on a precise roller arrangement carried on accurately machined rails mounted to the main yoke structure with provision for empirical micro adjustment. Since the magnetic forces would be quite large, more than 5 tons, a powerful mechanism had to be devised to adjust the gap opening. We settled on a hydraulic solution. The main hydraulic cylinders were surplus US Air Force B-17 aircraft landing gear shock struts purchased for \$10 apiece. A surplus hydraulic pump was also acquired to supply the

Figure 2 The Stanford permanent magnet for high-resolution NMR spectroscopy (Reproduced by permission from *Physical Review*, 1956, 102(1), 136)

motive power. The entire magnet was mounted on a wooden cart of massive proportions which rolled on three wheels, again surplus, originally used as tail wheels for the Navy SB-2-C dive bomber (\$4 each). A drawing and photograph of the magnet are shown in Figure 2.

The Alnico bars were seated in the respective poles, nine bars, each about 14 in. long and of 4×4 in. section, to each pole. We felt it essential to control the geometry of the Alnico faces as well as possible in order to achieve the best uniformity of field ultimately in the gap. To ensure the geometrical precision, it was necessary to grind the Alnico bars in place, and since we had no grinder available to do this we improvised an outboard grinder from a defunct milling machine. Patience delivered what we deemed a usable geometry. Alnico is very hard and subject to spalling, so patience was required to achieve the Alnico faces needed. Calculations of the field to be expected from the Alnico, and the need to provide smoothing of local perturbations of field on the Alnico faces, led us to provide pole caps shaped and tapered to reduce the area of the gap by about 10%. The caps were made of two slabs of heat treated very pure Armco 'ingot iron' which was said to be very uniform and magnetically soft, and could be expected to smooth out field irregularities occurring at the

Alnico faces. The pole caps were carefully machined and were ground flat and parallel in an outside shop, this being the only 'outsourcing' that was undertaken in the magnet construction. Finally assembled and resting on its wooden carriage, the magnet was complete although not 'charged'.

The charging of the magnet was accomplished with a closed gap, using copper coil windings preassembled on the poles with a calculated minimum of copper and a maximum of current. Again, in the interests of holding costs down, the magnet was energized using local and borrowed facilities. The laboratory was near an electrical substation at Stanford where three-phase 60 cycle 4360 V power was available. To use this source, we benefited from the kindness of Varian Associates who loaned us six large ignitrons to rectify and switch power. The expected current would be about 400 A, giving a power level of nearly 2 MW. The magnetization was carried out at 1 a.m. so that the surge (and possible actuation of circuit breakers) would not be noticed by other members of the Stanford community. Energizing the magnet required application of current for less than 1 s to provide a magnetizing force sufficient to saturate the Alnico.

In order to confirm that sufficient magnetizing force had been applied, at the suggestion of Professor Bloch a single turn of wire had been thrown around the pole structure and connected to a 19th century ballistic galvanometer from one of the student laboratories. As the galvanometer delivered the expected reading, we were confident that magnetization was achieved and we disconnected the charging circuit. Later, when the gap was opened, measurements of the field produced very welcome numbers. The final field in a gap of about 1.5 in. was sufficiently above 7000 G that we could apply the prescribed stabilizing demagnetization, a step that brought the nominal field to a value suitable for 30 Mc/s proton resonances.

The performance of the magnet was very gratifying. Stability was considerably improved compared with the electromagnet earlier used, although we were beset with a livable but inconvenient long-term reversible variation resulting from temperature changes. Also, the properties of the magnet with the necessary long poles of low permeability Alnico did not provide as much magnetic shielding as would a comparable electromagnet with soft iron poles. To counter these two problems, we determined first the times when the temperature effects were minimum (very early in the morning) in order not to compromise the linearity of the very slow sweeps that were necessary as the lines became narrower. For the slowest sweeps, on occasion, we actually used the thermal drift which was extremely steady, if not altogether linear.

The harmful effect of diminished shielding was to admit fluctuations of the field when an operator moved in the laboratory, he carrying the usual burden of keys, shoe nails, belt buckles, pocket knives, tools, etc. The perturbation of the field resulting from the operator moving about was sufficient to displace lines in the spectrum by unacceptable amounts. When data for record were acquired, the operator (me) stripped (with a bit more than necessary drama) to underwear in order not to disturb the field.

To furnish the most uniform field in order to achieve high resolution of spectra, a number of measures were undertaken, some of which were rational and productive. The sample used was made as small as the low signal level would permit. The materials used in the NMR 'probe' comprising the housing of the crossed coils, the coils themselves, and all of the parts

that were anywhere near the sample had to be selected for complete absence of any ferromagnetic material and for the lowest possible magnetic susceptibility. Parts were cleaned in dilute HCl to digest any small particles of iron that might have been left from machining processes. The need for these precautions may be appreciated with the recollection that a $10\mu\text{m}$ ferromagnetic particle saturated in a large magnetic field will produce a field gradient comparable to chemical shifts at 1 cm distance, and for 'nonmagnetic' materials, even diamagnetic susceptibilities are in the parts per million range and could influence the field adversely at the site of the sample when linewidths are less than one-tenth of this figure.

The disparity of the lowest possible susceptibility to be found in materials for the probe and the requirement for spectral resolution was resolved by observations of Professor Bloch and others (I particularly remember discussions with Harry Weaver and Martin Packard) to the point that in a magnetic field originally uniform, the introduction of a body of uniform susceptibility and circular (or ellipsoidal) geometry will provide that within the body the field will also be uniform, although slightly decreased for diamagnetic bodies. The field outside the body will be distorted to bring about this accommodation. At the point of this observation and onward, NMR probes were designed with religious observance of the need to surround the sample with nested sections conforming as far as possible to spheres or long cylinders.

Many other measures were undertaken to improve the quality of the spectra. Two stand out, one being a logical correction process to improve the quality of the magnetic field, namely, the introduction of adjustable 'current shims' which could add small changes to the local field gradients in order to bring about greater uniformity. The original shims were of crude geometry and haphazard operation. Current shims have since been very much refined, now being constructed according to an appropriate geometrical expansion of terms devised to furnish a nearly orthogonal set (less than complete) up to the fourth order. The original current shims, which were simply circular, did make it easier to maneuver the field and the location of the sample in the field, albeit with very tedious, nonconverging adjustments, to improve the lineshapes.

The second measure to improve the lineshape was an outcome of a leap of intuition on the part of Professor Bloch. He called me into his office one afternoon and said that if a means could be devised to stir up the sample in a time short compared to broadening of the line brought about by variations of the magnetic field (measured in units of the reciprocal proton frequency) the lines should be narrowed accordingly inasmuch as the nuclei would sense just the average magnetic field. As in all of the best inventions, once said, the logic of this concept was obvious, and I set to work immediately to make a tiny paddle wheel to stir up the sample (which at that time was held in a 4 or 5 mm tube). The paddle was made up of glass, possibly not the best choice of material in view of its necessarily unfavorable (noncircular) geometry and uncertain magnetic susceptibility. The little paddle was attached to a tiny turbine by a long glass shaft and was spun by a stream of argon gas. (We had a cylinder of argon that had been just a little used and was available. At our very low rate of consumption that abandoned resource lasted more than a year.)

By 11 p.m. I had the first results and observed notable improvement from the very first application. The greatest improvement was transient each time the turbine was turned

on, although considerable improvement was sustained for as long as the stirring continued. We quickly understood that the initial kick of starting the turbine provided a more thoroughly random stirring of the entire sample, while the steady state provided only rotation. In the steady-state condition, there was no averaging of fields along the axis of rotation and the gradient in that direction brought about a residual broadening. Sample 'stirring' was accomplished in later versions just by spinning the sample tube itself, the geometry of the tube conforming to the required circular section, with no paddle inside to disturb the magnetic field. This approach provided very effective averaging in the azimuth of rotation, and the operation to improve lineshape was simplified to the extent, in this order, that only variations along the rotation axis needed to be adjusted or compensated.

The outcome of these moves, and a lot of patience, was a very satisfying exploration of the ethanol molecule. The luck of natural constants, expressed first in the value of the chemical shift perturbations, held further as we were able to resolve the interior structure of the three originally observed chemically shifted lines. The chemical shift originates in the local diamagnetism of electron orbital motion at the three chemically distinguishable sites in the molecule. A second perturbation, quantum mechanical in character and different from the chemical shift, gives rise to a discrete splitting of the chemically shifted components independent of the main magnetic field. This perturbation is called spin-spin interaction.

In the Hamiltonian description, this interaction can be expressed as a separate and different energy term involving the quantized angular momenta of the chemically shifted groups, and for ethanol (and many other organic samples) the energy of the perturbation is conveniently smaller than the chemical shift term (in the range of magnetic fields used at the time) by about an order of magnitude. Including the dominant term due to the moment of the protons in the primary magnetic field, there are three energy terms with successively decreasing values in the Hamiltonian description. This circumstance leads to a very convenient Hamiltonian analysis, using perturbation methods, of the spectral properties to be found in the experiment. When a Hamiltonian description is undertaken with the dominant interaction of nuclear moments in the main magnetic field, and with the two added terms representing chemical shift and spin-spin interaction, respectively, the finer displacements and multiplicity of the energy levels can be computed by perturbation theory. With the interaction with the main field described as the first-order solution, the results of the perturbation calculation conform very well in the number, locations, and amplitudes of peaks, to the best resolved spectra observed in experiment, with the calculation taken to the third order in the perturbation expansion.

In the first order of the spin-spin energy term (the second-order perturbation of the main term of the Hamiltonian), we expect, and see in the experiment, the component of the methyl group of protons to be split into a triplet, representing the three quantum mechanical combinations of spin of the two protons in the adjacent methylene group. The component of the spectrum due to the methylene group can be doubly split by the influence of the four combinations of spin of the three protons in the methyl group compounded with the two states of the proton in the hydroxyl group. Indeed, in the right circumstance, at this level of resolution eight lines can be seen

experimentally, along with the expected tripling in the group of lines due to the hydroxyl proton.

As higher resolution was achieved experimentally, additional splitting was revealed. For example, in the methyl group, the three peaks resolved in second order were themselves split, the central peak showing a doublet and the two side peaks showing triplets. This further structure conformed faithfully to the results of the next order of perturbation calculation with constants already determined from the first-order displacements observed. These aspects of the spectra furnish a very nice confirmation of the quantum mechanical behavior of the ethanol system in the NMR experiment.

The frequency interval of the splitting at this level was in the scale of a fraction of a cycle per second, and with the broadening of lines due to spin-lattice relaxation no further splitting or displacement could be resolved. In order to obtain spectra at this degree of resolution, very long sweep times (extending typically to 30 min) were used, and all of the tricks that we could devise to maintain stability and uniformity of field had to be invoked. Figure 3 shows ethanol spectra progressively better resolved along with the calculated values for the peaks taken to successively further order. Except for an artifact of a slightly nonlinear sweep at the highest resolution, agreement between the calculated and observed spectra is very good.

The study of ethanol yielded one additional dramatically significant observation. On occasion, when the resolution of the methyl group was very good the resolution of the methylene and hydroxyl groups seemed equivocal. In other experiments, the methylene group showed a reasonably sharp first-order splitting to only four lines, while the hydroxyl proton furnished a single sharp line. Experiments varying the 'pH' of the ethanol by adding very small amounts of HCl and NaOH and with slight dilution with water led to a graded series of spectra with second-order splitting into four components for the methylene group with a single hydroxyl proton line at one extreme, and with eight methylene components and the hydroxyl proton 'group' split into three components with nearly the same sharpness as the finest lines of the methyl group.

These phenomena were explained by presuming an exchange process for the hydroxyl proton at rates that were dependent on the chemical matrix surrounding the ethanol molecules, most pointedly expressed in the 'pH' of the sample. The model used in the explanation presumed that the hydroxyl proton of ethanol could exchange with free hydrogen ions in the matrix, originating either from water or from trace addition of acid or base, or even from dissociated ethanol. The rate of exchange would be proportional to the number of free ions in the matrix. In the 'purest' samples, the rate of exchange was less than the spin-spin splitting (defined in frequency units), and the hydroxyl protons of ethanol were associated sufficiently long to define the states leading to the structural features of the associated hydroxyl spectral group. When there were sufficient numbers of free ions in the matrix, on the other hand, exchange events were much more rapid, and the residence time of the hydroxyl protons was so short that their interaction was simply averaged over the ensemble of states in the methylene groups of the many ethanol molecules visited. Under these circumstances one would find the hydroxyl proton line discrete and narrow as in a free proton, and the corresponding spectral presentation of the methylene group would

Figure 3 Spectral lines for ethyl alcohol in successive steps of resolution. (a) Resolved to first order (chemical shift) with calculated spectrum. (b) Resolved to second order showing the gross spin-spin splitting. The hydroxyl proton association time is short. (c) Second-order structures with association time sufficient to exhibit the interaction of methylene and hydroxyl proton. (d) Third-order structure resolution of the three chemically shifted groups with the positions and amplitudes of lines calculated to third order with the two extremes of hydroxyl proton association (Reproduced by permission from *Physical Review*, 1956, **102**(1), 136)

be found structured only as to the interaction with the methyl group permanently attached.

This observation of the exchange event could be carried through a range of association times, beginning with the longest (of the range 1 s or greater) in 'pure' ethanol with sharp lines, through samples that exhibited association times (in range a few tenths of a second) comparable to the reciprocal of

Figure 4 The effect of association time in the hydroxyl proton. Intermediate cases were calculated for comparison. In the third spectrum, the association time must be about 1 s (Reproduced by permission from *Physical Review*, 1956, **102**(1), 136)

the spin–spin interaction (expressed as frequency), ultimately to very rapid exchange times (above 10 per second). The sharp lines at the extremes have been described. At the intermediate range, the lines of the methylene and hydroxyl groups were actually broadened enough almost to obscure the splitting corresponding to the second-order (spin–spin interaction) calculation of energy levels, even though the lines in the methyl group showed good resolution of fine lines. At the extremes of fast exchange, the line structure of the methylene group showed the splitting corresponding to the second-order calculation split only by the adjacent methyl group. Figure 4 shows the theoretical and experimental spectra for the three cases.

The magnet used for these experiments had an interesting career. It was used for two additional Ph.D. theses under Professor Felix Bloch, one of which was the definitive standout work of Weston Anderson. In 1954, the European Centre for Nuclear Research (CERN) was inaugurated in Geneva, Switzerland. Professor Bloch was invited to be the first director, and, to maintain continuity for his students, he asked that two of us (Weston Anderson and myself) and the equipment for high-resolution NMR be transported to Geneva to continue the work. I had just finished my thesis, and Anderson was in the final processes of his work. When we were invited to accompany Bloch with the equipment, needless to say we accepted the opportunity with enthusiasm!

Beginning in Geneva, and continuing thereafter at Stanford for something over two years, the magnet and the equipment were used for experiments extending the work on simple

organic molecules. Examples were chosen to illustrate particular aspects of the energy relationships, with Anderson's particularly penetrating methods using multiple frequencies. Additional experiments in Geneva and later at Stanford with a variety of timed excitation sequences began to explore time domain NMR, explicitly not to say at this stage as yet anything resembling transform spectroscopy.

At Stanford University after the final graduate student, the magnet was retired. Shortly thereafter, Stanford received a request that it be turned over to the Smithsonian Institute where it now waits for possible inclusion in a historical display of 20th century scientific events.

In keeping with the narrative character of this writing, I have, for the most part, omitted literature references. Clearly the work that took place at the time was carried out at several institutions in a very open environment of communication and publication. I have focused on the work taking place at Stanford University. Additional groups were also very active, and much of the accomplishment of the times must be credited to the many other members of the NMR community as a whole.

It is most appropriate in closing, as I speak for myself and for other members of the Stanford NMR cadre, emphatically to express appreciation for Professor Felix Bloch as a person of graceful humanity, culture, and personal kindness, and to recognize his truly exceptional qualities as a great physicist. As a gifted scientist of truly outstanding stature he was known and appreciated by a wide range of professional fellows. We, his students, were a very privileged few.

Bain, Alex D.: Early Development of Homonuclear 2D NMR (From the Outside)

Alex D. Bain

McMaster University, Hamilton, Ontario, Canada

The central mystery of pulse and Fourier transform NMR has always been the effect of a pulse on a system of nuclear spins. Pulse sequences are made up of both pulses and delays, but the evolution during a delay is relatively straightforward. In the absence of any rf, the various transitions simply oscillate at their resonant frequency and decay. A pulse is more complex.

The development of 2D NMR required an understanding of a pulse. First of all, what does a pulse do, and second, how can you control it? What a pulse does can still be mysterious and counter-intuitive, even if the rf terms dominate all the others in the Hamiltonian (a 'hard' pulse). The simple vector picture often works, but it breaks down just when you need it. This later spawned many theoretical descriptions of the effects of a pulse.^{1,2} The development of one of these, the superspin formalism,² was guided by two important papers, both from Ernst's group.^{3,4} I think they laid many of the foundations of pulse and multidimensional NMR.

The first paper³ discussed flip angle effects in Fourier transform spectra. In principle, FT spectra resemble the true spectrum only in the limit of small flip angles. Nobody used small flip angles, and the fact that your very new and very expensive Fourier transform spectrometer might not give the same spectrum as your old reliable CW machine was perhaps somewhat disturbing at the time. That particular problem was not serious, as it turned out, but this paper was one of the first to point out how much difference there is between the way a coupled spin system responds to a pulse and a delay. A doublet evolves as two lines during a delay, but during a pulse it is much better to think of a doublet as the sum of the two lines and the difference between the two lines. As we see from polarization transfer experiments, it is the differences amongst members of a multiplet that are the most interesting and which are responsible for the most important phenomena.

These flip angle effects provided an early case where the response to a pulse had to be considered correctly. A pulse is equivalent to a rotation of the frame of reference, but in the simple vector picture it does not much matter whether the magnetization is rotated one way or the frame of reference is rotated the other. For a coupled spin system, the distinction is crucial—it must be the frame that is rotated. This is because the spin that is being observed and the spin that is causing the splitting are both being rotated simultaneously. This is where angular momentum and spherical tensors come in. They provide an elegant and complete way, via Group Theory, to describe what happens to anything when the frame of reference is rotated. A spherical tensor description of NMR transitions is then a natural way to describe a pulse. Spherical tensors had already been introduced into NMR to simplify relaxation calculations,⁵ but they turned out to be much more useful for spin dynamics because of their rotation properties.

The angular momentum arises because a transition between two spin states inherits the combination of the spin angular momentum of the initial and final states. This angular momentum of the transition was dubbed superspin,² by analogy with superoperators in Liouville space. It is an angular momentum like any other, with a length and a z component. This then provides a complete way of describing a pulse, with no restrictions on whether the spin system was weakly coupled or whether the pulse phase or flip angle were multiples of $\pi/2$.

The second important paper represents the first use of phase cycling in a nonintuitive way.⁴ Phase cycling schemes such as CYCLOPS had been used for a long time, but these could be understood relatively easily with vectors. Even though COSY is implicit in the first papers on 2D, it is arguable that this paper on SECSY represents the first homonuclear shift correlation. While this paper was being published, homonuclear shift correlations had been observed, basically as artifacts in J -resolved spectra,⁶ but there were two copies of the spectra which came to be known as P and N type peaks. The SECSY paper showed how one set could be eliminated by cycling the mixing pulse. Even though it is quite easy to show mathematically why this works,⁷ it is difficult to have a good physical picture.

Phase cycling is a critical part of all pulse sequences. Still, however, there is no perfect way to design a phase cycle for a given pulse sequence. It is easy to put one together, based on some simple principles and experience. It is also straightforward to analyze whether it will work or not. However, there is usually some redundancy in these schemes and no clear way to get some sort of a minimal scheme. In general, however, phase cycling works very well in producing reliable, robust pulse sequences.

These two papers,^{3,4} although not often cited, represent the real foundations of two-dimensional NMR, in my opinion. The combination of what a pulse does, along with what we can do to control it by phase cycling, provided all we needed to know.

Balaban, Robert S.: Personal Perspective on the History of NMR

Robert S. Balaban

*National Heart Lung and Blood Institute, National Institutes of Health,
Bethesda, MD, USA*

I began my involvement in NMR with a NATO fellowship in 1980 to work in Professor George Radda's laboratory at the University of Oxford. At that time George's laboratory was very active in renal biochemistry studies in collaboration with Brian Ross. This research related to my thesis work on optical spectroscopy studies on the kidney. Upon my arrival Joe Ackerman had just finished his work on the development of the surface coil, which truly opened the door to many in vivo NMR biological applications. The laboratory was a unique environment where physicists, chemists, biochemists, and myself, the lone physiologist, were trying to learn from each other in this highly multidisciplinary field. It was a marvelous scientific environment, which illustrated to me the importance of these multidisciplinary approaches in the biological sciences. During this time J. Waterton and D. Gadian were developing B_1 field spectroscopic imaging techniques, and K. Thulborn was showing that the relaxation properties of water could be used to monitor blood oxygenation and flow in situ, a procedure that would take almost 10 years to be fully developed in humans. Numerous studies were being conducted on the perfused heart, including the measurements of the cardiac ATP synthetic rate by P. Matthews.

My own work was mostly learning the physics and hardware associated with NMR, as well as ^{31}P NMR studies concerning the energetics of isolated renal tubules and mitochondria (with Gordon Wong). We also had a lot of fun trying to combine optical and NMR spectroscopic studies of metabolism on simple systems. The magnet schedule (a wide bore 180 MHz prototype) was two 24-h blocks every two weeks. Thus, I would spend all day and all night making mitochondria or renal tubules to run on the magnet. Of significance in these studies was the determination of phosphate metabolite distribution in the mammalian kidney and the visibility of ATP in the mitochondrial matrix. One morning, after a particularly long 24 hours of liver mashing, we were approached by a maintenance man in the building politely requesting the return of his floor polisher from the newly energized 2 T wide-bore magnet down the hall It turned out to be an even longer day . . .

From this initial experience in George's lab, it became clear that you should not only keep the door locked to your spectrometer but that NMR would provide an extremely important tool in the study of physiology. Upon arriving at the NIH in 1981, the scientific director of the NHLBI, Dr. Jack Orloff, was also convinced of this potential and began the NHLBI biological NMR program by purchasing a wide-bore 360 MHz magnet for the Chemistry Laboratory. I still remember the looks of horror as Jim Ferretti and Bob Highet watched me place the first live rat in their treasured new instrument. This began a very productive collaboration with Jim Ferretti in the utilization of 2D NMR techniques in the evaluation of complex enzyme kinetics in vitro and in vivo

even though Jim still entered the room only after the rat was in the magnet . . .

During this time the serendipity of the biological applications of NMR spectroscopy became very clear. In one of our earliest studies we performed a series of studies with ^{14}N NMR attempting to measure the concentration and distribution of urea in the intact kidney (with Mark Knepper). However, our studies revealed a very broad and not very useful urea ^{14}N resonance (exchange broadening), but an extremely sharp and intense resonance in the region of trimethylamines. After a week of library and telephone interviews it was clear that no-one knew what this compound was in the kidney in the 20–80 mM concentration! It turned out to be the oxidation product of choline, betaine, and its discovery started a new area of research in renal studies on the role and regulation of these organic osmolytes in the protection and function of the kidney. Another serendipitous result was the discovery that adenylate kinase produces quaternary adenosine phosphate under physiological conditions (with Jim Ferretti and V. Kuprianov). These results clearly demonstrated that the scanning nature of the NMR experiment is of great value to the biologist since it provides information on parameters he/she would not have had the prior knowledge to suspect to be an important parameter. This has the important implication of showing the investigators a new direction which could have not been predicted a priori.

Dr. Howard Kantor arrived in my lab as a clinical associate. After attending the first SMRM meeting, where the difficulties of obtaining localized spectra from the heart were discussed, Howard suggested that if a coil could be fabricated on the end of a catheter he could get it into the heart to collect the localized spectroscopic data. Indeed, the quote I remember from Howard was 'To tell the truth, a coil would not be a big deal, you should see what we put in patients' hearts'. After designing several different coils, we finally reached our design specifications after numerous visits to the local plastic shops trying to find the best insulator and a small 50 Ω nonmagnetic coaxial cable. Next we needed a high field magnet large enough to fit a dog. At this time there were very few wide bore magnets capable of making this type of spectroscopic measurement. Thankfully, Dr. Richard Briggs had a 2 T system at the Hershey Medical Center, two and one-half hours north of Washington, and he agreed to collaborate on this project if we provided the animals. This resulted in many enjoyable trips to the chocolate town with premeasured animals in tow which would fit in Richard's magnet. Despite Howard's claims, the placement of the coil was not trivial, and we spent many, many hours in the rather hot catheterization lab wearing very heavy lead aprons working on the catheter coil placement. I think my lower back suffers more from that experience than the foolish years of football earlier in life However, in the end a very simple and robust procedure was developed which resulted in some of the earliest ^{31}P NMR studies on the effects of cardiac work on high-energy phosphates in vivo.

With our successful dog experiments, the NIH lab was expanded to include a 30-cm bore 4.7 T system with imaging gradients, and a new laboratory, The Laboratory of Cardiac Energetics, was created. Many fellows working on spectroscopic applications came through the lab at this time, including Alan Koretsky, Larry Katz, Fred Heineman, Dave Kim, Tom Scholz, Teresa Kassera, Maren Laughlin, and Mike Portman. These studies involved numerous aspects of cardiac energetics,

including cardiac cycle studies, hormonal stimulation, development and metabolic substrate dependencies. Indeed, this program is still a very large part of our research program today, and as a brief survey of the physiological literature will currently reveal, NMR has in general become a standard tool in the evaluation of physiological function.

Imaging gradients in the 4.7 T system provided a new tool into performing metabolic imaging studies. Two medical students, Paul Hsieh and Steve Wolff, started in the lab with an intense interest in imaging and began our metabolic and functional imaging program. With our long-standing interest in enzymatic rate measurements, it was not surprising that our first work was the generation of creatine kinase activity maps in the intact rabbit leg using ^{31}P NMR imaging. This was quickly followed by one of the first 'functional images' of the body, when Steve demonstrated the three-dimensional topology and kinetics of sodium washout during diuresis in the in vivo kidney using ^{23}Na NMR.

Our success in this rate constant imaging resulted in a late night discussion of transferring these ideas to ^1H studies. Our preliminary studies showed that we could improve the signal-to-noise of ammonia or urea detection by ^1H NMR by factors in excess of 1000 by using saturation transfer techniques, monitoring the exchange of water with these metabolites. In a field where improvements in S/N are usually measured in terms of factors of two or less, we were very excited about the use of this approach in vivo. Steve's first in vivo experiments were very successful, and large reductions in the water resonance were observed when he irradiated at the NH_3 or urea chemical shifts in the in vivo kidney. The problem was that no matter where Steve irradiated, over almost a 40 kHz bandwidth, a strong saturation transfer effect was detected on the water resonance. Furthermore, the distribution of this interaction did not track the concentration of ammonia or urea in the kidney. After several weeks of confirming that this was not due to some bizarre artifact in our sometimes reliable spectrometer, we confirmed that this was a real phenomenon with a defined bandwidth and spin lattice relaxation effect on the water protons. We quickly realized that this effect was not due to the presence of numerous exchanging metabolites in tissue, but must be due to a magnetization transfer effect between the solvent water and restricted motion protons associated with the macromolecules of the cell. These studies eventually led to

the development of magnetization transfer imaging techniques, where the signal intensity in an image is modified by the degree of dipolar coupling to the macromolecular matrix, resulting in magnetization transfer contrast. Several fellows beside Steve and Paul provided key insights into this area, including Toni Ceckler, John Eng, and Teresa Fralix. The almost immediate clinical application of this laboratory result was also a very rewarding as well as surprising event since, as most basic researchers, we never expect our studies to have such an immediate impact on clinical practice.

The numerous successes around the world in the biological applications of NMR at 4.7 T and higher fields suggested that high-field (>1.5 T) studies on humans might be feasible and perhaps desirable. Several of the manufacturers had reached the same conclusions and had begun 4 T projects, which in 1987 were ready for more application studies and less technical development. After Dr. Orloff and Dr. Claude Lenfant, Director of the NHLBI, secured funding to begin a 4 T program in the NHLBI, a whole body 4 T system was purchased. This system was installed at the NIH in 1990 and after significant technical modifications has shown that our initial impression concerning the advantages of high magnetic fields in humans was correct. These studies have included functional imaging of the human brain with Bob Turner and Peter Jezzard, as well as a whole host of spectroscopic studies on the biochemistry and composition of the human body. Clearly the advantages of high field greatly helped our understanding of human biochemical and physiological function. However, much is left unknown.

Biographical Sketch

Robert S. Balaban. *b* 1953. B.S., 1975, Ph.D., 1980, Physiology and Pharmacology, Duke University, USA. First experience in NMR during postdoctoral fellowship with G. Radda at University of Oxford (1981). Joined National Heart Lung and Blood Institute NIH in 1982. Currently Chief, Laboratory of Cardiac Energetics. Approx. 200 publications. Research specialties: macromolecule/water magnetization transfer, in vivo NMR applications, coil development, tissue energetics, mitochondrial respiratory control.

Barfield, Michael: Thirty-Three Years of NMR Parameters

Michael Barfield

University of Arizona, Tucson, AZ, USA

In 1957 I had an encounter with a 40 MHz Varian NMR spectrometer (while employed at General Dynamics in San Diego), but it was a few years later that I actually started using NMR. In 1960 I joined the research group of David M. Grant at the University of Utah. Dave had recently joined the Chemistry Department as an assistant professor after completing a postdoctoral fellowship with H. S. Gutowsky and Martin Karplus at the University of Illinois. A project of immediate interest to me was the H–C–H angle dependence of geminal H,H coupling constants. Based on the H,D coupling constants for a series of deuterated compounds, it soon became apparent that this type of coupling was more sensitive to the number and orientation of adjacent substituents than to the H–C–H angle. Our attempts to use semiempirical valence bond theory to understand these factors were not successful until it became obvious that these types of geminal coupling constants were negative in sign. This was demonstrated by the relative sign measurements of Frank Anet and others reported at the NMR meeting in Boulder, Colorado in the summer of 1962.

After completing the Ph.D. work at Utah in 1962, I joined John D. Baldeschwieler's group at Harvard University as a postdoctoral associate. This research was in the general area of nuclear magnetic double resonance (NMDR) and it presented the opportunity to learn more about the instrumental and phenomenological aspects of NMR. When I started to look for a job, some of the industrial interviews were cancelled because there appeared to be no obvious applications for NMDR techniques. At Shell Development Company in Emeryville, CA, the person making an offer said that if I accepted an assistant professor position at the newly created University of South Florida (USF) in Tampa, I would never be heard from again.

At USF my attention returned to the theory of nuclear spin–spin coupling. It appeared that the conformational dependence of long range H,H coupling constants could also be explained via valence bond (VB) methods. During this period there developed a correspondence with Martin Karplus, which was to continue for several years and which was concerned, in part, with the popular misconceptions of the factors affecting *J* couplings. These problems were especially apparent in the often used and misunderstood terms 'through space' and 'through bond', which we defined in terms of a VB bond order formulation.

In 1964 I came across a paper entitled 'The Spatial Correlation of Electrons in Molecules' by J. E. Lennard-Jones (*J. Chem. Phys.*, 1952, **20**, 1024) which stimulated my interest in using density matrix techniques to study NMR parameters and the effects of electron correlation on *J* couplings. Following a move to the University of Arizona (1965), density matrix techniques were used to simplify previous MO and

VB derivations and to develop new procedures including a VB formulation with an explicit sum over triplets. These methods were used for a large number of our studies, especially for factors affecting long range H,H coupling constants, *J* anisotropies, and studies of hyperfine coupling constants. In the 1960s a considerable effort was put into modifying the old polyatom SCF–MO program for use on our local computer to perform ab initio calculations of *J* couplings (Joanne Reed, Ph.D., 1971). Our ab initio results were consistent with those of other groups in demonstrating inadequacies at the Hartree–Fock level, and were abandoned in favor of semiempirical methods.

In 1969 Sever Sternhell (University of Sydney) came to Tucson to discuss long-range coupling constants. This was the beginning of a more than 25 year collaboration. In the period 1970–71 Milton D. Johnston, Jr., a postdoctoral fellow (now at USF), developed techniques for describing solvent effects on nuclear spin–spin coupling constants. These models, which made use of coupled Hartree–Fock theory and semiempirical MO methods, went through increasing degrees of sophistication starting with a reaction field model, a cluster model, and then a rotating cluster model. In 1972 I returned to the laboratory to learn the intricacies of Fourier transform NMR. This quickly led to collaborations on ¹³C–¹³C coupling constants with David M. Doddrell (then at Griffith University, Brisbane) and James L. Marshall (North Texas State University). During the period 1974–76, with the encouragement of Dave Grant, we became interested in the theory of chemical shielding and chemical shielding anisotropies.

During my sabbatical in Australia (1976–77) and David Doddrell's sabbatical in Tucson (1977–78) we investigated, with the mathematical expertise of Hans P. W. Gottlieb (Griffith University), some aspects of relaxation in paramagnetic species and structural effects on deuterium quadruple coupling constants. Experimental and theoretical studies of NMR parameters in bicyclic compounds were part of collaborative efforts with Ernest W. Della (Flinders University, Adelaide) and N. Dale Ledford (University of South Alabama). These and other experimental ¹³C NMR studies in Arizona were accomplished by some outstanding graduate students including Stephen R. Walter (Ph.D., 1982), Abdulla S. Babaqi (Ph.D., 1982), and Lung-Fa (Jeff) Kao (Ph.D., 1983). Another experimental program initiated in 1979 used ¹³C NMR to investigate polymer microstructure, especially for unusual species having all cyclobutane rings in the backbone. Key players in these studies include H. K. Hall, Jr. of this Department, Jeff Kao, Ray J. H. Chan, and visiting scientist Yinghong Mou.

With the help of Julio C. Facelli (visiting scientist, now at Utah) we continued with studies of *J* couplings. Our most recent effort on *J* coupling (in collaboration with William B. Smith, Texas Christian University) concisely demonstrates the way in which vicinal H,H coupling constants depend on both H–C–C angles and dihedral angles.

Following a sabbatical year (1986–87) in Germany, the major new areas of interest have been concerned with ab initio MO studies of chemical shielding emphasizing conformational dependencies of ¹³C chemical shifts. The ab initio MO studies of conformational effects for chemical shifts in lactams and peptides were accomplished with the help of Ding Jiao (Ph.D., 1993). We have also used local origin methods in trying to understand transition metal shielding, especially

for molybdenum compounds in collaboration with John H. Enemark and a postdoctoral associate Jaime E. Combariza.

GETTING STARTED

Ever since NMR was first discovered, NMR spectroscopists have been battling the technological problems that present the major barrier between creativity and experimental results. In the early 1970s, Toon Mehlkopf in the Applied Physics Department at the Delft University of Technology, The Netherlands, got so frustrated by the technical limitations of commercial NMR equipment that he decided to design and build one himself, the so-called 300-MHz project. The system included four home-built synthesizers and was controlled by a Hewlett Packard 21/M20 computer with 32 kbyte of memory. It was designed to be capable of both CW and pulsed NMR, including such important techniques as spin tickling, rapid scan correlation spectroscopy, DEFT and SEFT experiments, and a long list of other experiments that have long since been forgotten. In 1975, I was lucky to be accepted by Toon to work as an undergraduate student on the development of the pulse programmer and the data acquisition software of his spectrometer. Indeed, once completed in 1977, this spectrometer was capable of performing virtually any experiment. It also could acquire FIDs of up to 300 k Word at speeds of up to 45 kHz and average those to data stored in double precision on the disk. It also could execute pulse sequences of arbitrary length and complexity.

In the summer of 1977 when our group leader, Jaap Smidt, returned from a conference where he had heard Richard Ernst speak about two-dimensional NMR, our spectrometer was put to the true test. The main hurdle, it turned out, was for me to understand what Aue, Bartholdi, and Ernst were talking about in their historic paper.¹ After it slowly started to dawn upon me, it was relatively little work to write the required pulse program and data matrix transposition routine. About four weeks after Smidt's return, we had our first homonuclear J -resolved 2D spectrum.

When the next spring Mehlkopf and Smidt suggested that I continue to work for a Ph.D., I was excited about this opportunity, as well as by the idea that this would postpone my national service by at least four years. My only fear was that 'all experiments had already been invented', so what was I supposed to work on?

My first two papers were the result of a two-day trip to Zürich, where I visited the labs of Richard Ernst and Kurt Wüthrich. After Alex Wokaun very patiently but in vain had tried to explain to me the principles of multiple quantum NMR, I got into a heated debate with Kuniaki Nagayama, then a postdoc with Wüthrich, about obtaining absorption mode homonuclear broadband decoupled spectra. According to Nagayama, and he was right of course, one cannot get such a spectrum from a skewed projection of a homonuclear

J spectrum because of the 'cross section projection theorem'. Back in the Netherlands, and still frustrated about having been 'set straight' by a biochemist, I came up with a way around this theorem: constant time spectroscopy. By keeping the time between the initial 90° pulse and the first detected data point constant and shifting the position of a 180° pulse [$90^\circ - (T - t_1/2) - 180^\circ - (T + t_1/2) - \text{Acq.}$], I obtained a homonuclear decoupled spectrum of ethanol, and my first paper.² Little did I realize at that time how useful this silly idea would become in heteronuclear NMR of ^{13}C -enriched proteins, where it is now widely used to eliminate $^1J(\text{C,C})$ couplings.³

Another esoteric idea that would later prove useful occurred to me after I had been wrestling my way through a stack of re-and preprints that Alex Wokaun had given me on my Zürich visit: pulsed field gradients. Clearly it should be possible to separate the different orders of multiple quantum coherence by means of pulsed field gradients. It took Toon Mehlkopf and electronics engineer Tom Tiggelman less than two weeks to build a pulsed field gradient device (with lock interruption) and implement it on the home-built 300 MHz spectrometer. Although the idea worked,⁴ eddy currents induced by the pulsed field gradients were a serious problem—self-shielded gradients had not yet been invented—and discouraged me from further pursuing it. Nowadays, in protein NMR there is virtually no experiment left that does not significantly benefit from the use of pulsed field gradients with self-shielded coils.

OXFORD BLUES

When Ray Freeman, frustrated by an antiquated CFT-20, heard about Mehlkopf's 300-MHz project, he promptly offered him a job. Fortunately for me, Toon was unable to accept and he suggested that I might be interested in conducting part of my Ph.D. work with Ray in Oxford. The next three years were tremendously exciting for me. Not only is Oxford considered a Mecca for oarsmen—one of my favorite sports—but it also proved to be a very exciting place to live, with long-reaching consequences for my future social life.

Ray's brilliant insight in NMR and his enthusiasm for science tremendously stimulated his research group and convinced me that science could be very enjoyable indeed. The coffee and tea breaks, which typically would take at least an hour, were the highlights of the day, to the great frustration of Gladys, the cafeteria manager, who never managed to close early and go home. My stay in Oxford coincided with that of Malcolm Levitt, Gareth Morris, Tom Frenkiel, David Max, Stewart Kempell, A. J. Shaka, and James Keeler. Needless to say, that this was a most inspiring working environment.

When I arrived in Oxford, Stewart had just come back from a conference where he had seen organic chemists measuring ^{13}C - ^{13}C coupling constants from the satellites in a ^1H -decoupled ^{13}C spectrum. There should be a better way to do this he argued, and as I was considered to be 'the' multiple quantum expert from my previous pulsed field gradient multiple quantum work, I was asked whether multiple quantum somehow could help. And that was how the INADEQUATE experiment was born.⁵ Although the concept of multiple quantum filtration was developed independently by the Ernst group,⁶ the INADEQUATE experiment stole the limelight, not in the least because of the acronym that Ray had come up with, which stands for Incredible Natural Abundance

Double Quantum Transfer Experiment. It was not clear at that time that the extremely lengthy 128-step phase cycle that we proposed was doing nothing else but eliminating the ' T_1 memory' of the spins. Because the delay between scans was not much longer than the ^{13}C T_1 , the z magnetization of the next scan would 'remember' the rf phases used in the preceding scan and therefore cancellation of the signal from isolated ^{13}C nuclei was not complete. By sheer coincidence, the order of the steps in the 128-step phase cycle would cause such effects largely to cancel.⁷ Unfortunately, our complex phase cycle led to the idea 'the more phase cycling, the better—no questions asked'.

THE MILE HIGH CLUB

On the recommendation of Ray I went on to do postdoctoral work with Gary Maciel in his 'Mile High Proton Enhanced Nuclear Induction Spectroscopy' laboratory in Colorado. I could not have made a better choice. Gary was extremely enthusiastic and supportive of my rather crummy attempts to apply some of the high-resolution ideas in solids, none of which happened to work out too well. I was lucky to be in Gary's group at the same time as Nick Szeverenyi, who had a true fascination with building gizmos. My original prototype of a magic angle hopping device consisted of rubber bands and Q-tips and required the operator to yank twice every scan on a nylon string. Nick's design and construction of a stepper-motor driven hopping probe made the experiment actually work.⁸ Another one of his challenging accomplishments at that time was the design and construction of a 'magic angle flipping' probe⁹ which would alter the orientation of the rotor axis between the magic angle and the xy plane, twice per scan. The anticipated problem, to keep the spinner going, posed no real difficulty for Nick. The main problem turned out to be that after every 100 000 flips or so, the leads connecting the coil to the tuning capacitors would succumb to fatigue. This 'flipping probe' allowed us to do a 2D experiment where the isotropic ^{13}C shifts are detected during t_2 and the associated CSA powder pattern, scaled by $-\frac{1}{2}$, in t_1 . The first powder patterns of dimethoxybenzene measured this way were highly distorted and exhibited some very unusual nonpowder pattern features. In search of the cause of the bizarre appearance of these patterns, I desperately—Waugh, forgive me—even started questioning the generality of 'coherent averaging'. Only by chance did we finally discover that these distorted patterns would turn 'normal' if one packed the spinner very tightly; otherwise the centripetal force of the spinner would cause a nonrandom orientation of the individual crystallites inside the rotor.

While I was studying the principles of solid state NMR, next door in the NMR Center Richard Griffey was trying to correlate ^1H and ^{15}N chemical shifts by selective coherent ^{15}N decoupling and observing the collapse of the imino proton doublets in ^{15}N -enriched tRNA. When Bruce Hawkins, manager of the NMR Center, mentioned this to me I knew there should be better ways to do this. Although in principle Geoffrey's 'Overboderhausen experiment' (aptly named that way by Ray Freeman during one of our tea breaks, but now better known as heteronuclear single quantum correlation, or HSQC) would permit ^1H detection of the ^{15}N resonances,¹⁰ an additional problem was posed by the intense H_2O solvent

signal; solvent presaturation was not possible because of rapid imino proton exchange. Heteronuclear multiple quantum coherence (HMQC) solved this problem and allowed us to do the experiment using only a single ^1H pulse which was adjusted to have a null in its excitation profile at the H_2O frequency. After discussing the pulse scheme with Bruce, he built an inverse ^{15}N channel literally overnight and the next day we obtained a 2D ^1H – ^{15}N correlation spectrum, first try! Even in retrospect this experiment, conducted on an old 360 MHz Nicolet spectrometer and using only 3 mg of a 25 kD macromolecule in H_2O , was quite impressive.¹¹ Although the same HMQC pulse schemes, together with a large number of alternative schemes, were proposed independently by the Australian group of Bendall, Pegg, and Doddrell,¹² the application of our experiment to a biological macromolecule and to natural abundance peptides was probably the main reason for the surge in popularity of these HMQC experiments. For me it was my first encounter with a biological application of NMR, and I liked it.

WELCOME TO THE GOVERNMENT

Although I loved Colorado, besides Gary Maciel none of the faculty at Colorado State were particularly impressed by my NMR experiments and I had to look for employment elsewhere. To my honest surprise, the National Institutes of Health offered me a tenure-track job. How on earth they could imagine that NMR, particularly the type of work I was known for, could benefit the NIH program was totally beyond me. Obviously, Ted Becker (the editor of this volume), Bill Eaton, and their colleagues at NIH had more foresight.

The first excitement occurred when Donald Davis, who had joined me for a sabbatical year, was trying to use Aksel Bothner-By's CAMELSPIN experiment¹³ to measure NOE interactions under spin-locked conditions in a cyclic peptide that gave miserable spectra with the regular NOESY method ($\omega\tau_c \sim 1$). This CAMELSPIN experiment later became better known as ROESY, for rotating frame Overhauser enhancement (ROE) spectroscopy. Yes, for many proximate ^1H pairs in the peptide we observed beautiful ROE cross peaks with opposite phase to the diagonal peaks. However, there were also a number of cross peaks in phase with the diagonal, in apparent conflict with Aksel's predictions. Most notably, the geminal nonequivalent C^δ protons of a proline residue in the peptide showed a very intense positive cross peak. Considering the short distance between the two C^δ protons (1.77 Å) we had expected a very intense ROE cross peak for this ^1H pair, so why would it be of the wrong sign and have an intensity that exceeded that of the diagonal? It was my solid state NMR experience that tipped us off to the real cause of these anomalous cross peaks: they were due to homonuclear Hartmann–Hahn cross polarization.¹⁴ Two resonances that feel the same spin lock rf field and that are J coupled should be subject to J cross polarization, just as in the heteronuclear case. Changing the offset and spin lock field strength indeed confirmed that these artifactual peaks were due to Hartmann–Hahn cross polarization. At the time, Donald and I suggested minimizing the Hartmann–Hahn artifacts by judiciously choosing the carrier position and the rf field strength.¹⁴ A much neater solution was later proposed by

A. J. Shaka, another Freeman pupil, which ‘spin locks’ the magnetization perpendicular to the rf field.¹⁵

Once we had recognized the origin of the Hartmann–Hahn artifacts, it was relatively straightforward to capitalize on them and use them for obtaining J connectivity. For maximum Hartmann–Hahn transfer the goal was to make the trajectories of the coupled spins as identical as possible. In retrospect therefore not surprisingly, our improved Hartmann–Hahn cross polarization schemes started to look more and more like heteronuclear decoupling schemes, where the objective is to make ^1H spins coupled to ^{13}C in the $|\alpha\rangle$ and $|\beta\rangle$ spin states undergo identical trajectories.¹⁶ The fact that the chemical shift difference between two J -coupled protons is typically much larger than $^1J(\text{C,H})$ makes the homonuclear Hartmann–Hahn (HOHAHA) cross polarization actually somewhat more demanding. Our initial attempt to publish the use of an MLEV16 mixing scheme was thwarted by a reviewer who argued, correctly, that the spectra had significant phase distortions and therefore were not all that useful. After a few more experiments it became clear that the artifacts were due to two distinctly separate effects. First, not only was the magnetization parallel to the y axis transferred from one spin to its coupling partner, but also the x -axis magnetization, albeit with a different efficiency. Second, even for a single noncoupled spin, for example the proton in chloroform, we found an offset dependent rotation about the z axis during the MLEV16 scheme, which at that time we naively attributed to pulse imperfections but which, as later shown by John Waugh,¹⁷ is inherent to the MLEV16 scheme. In any case, both effects were easy to eliminate: trim pulses ensured that the x magnetization was effectively eliminated. Adding a 17th pulse along the y axis after each MLEV16 cycle caused the average Hamiltonian to be dominated by this term and transverse magnetization could no longer ‘wander away’ from y and, voila, MLEV17 was born.¹⁸

While trying to develop our homonuclear Hartmann–Hahn (HOHAHA) pulse schemes it became clear that the concept was not new. Lukas Braunschweiler and Richard Ernst had several years earlier proposed the use of isotropic mixing in the so-called TOCSY experiment¹⁹ which accomplished magnetization transfer by means of a string of closely spaced 180° pulses. After its initial publication, this TOCSY experiment did not really ‘catch on’, probably because it did not work very well in practice. Although I am unaware of any detailed early studies on the efficiency of the TOCSY experiment, the general feeling at that time was that an experiment with so many 180° pulses should suffer from rf inhomogeneity and other pulse imperfections. However, the true reason for its poor performance can be seen by considering the string of 180° pulses as a homonuclear Hartmann–Hahn cross polarization. Due to the different offsets of the coupled protons, the rotation experienced by off-resonance protons is larger than that for on-resonance protons, causing a ‘Hartmann–Hahn mismatch’. Although even now the original MLEV17 mixing scheme still finds widespread use, more efficient mixing schemes have since then been developed by A. J. Shaka²⁰ and others, whereas Richard Ernst and co-workers devised an elegant scheme to eliminate ROE effects from macromolecule HOHAHA/TOCSY spectra.²¹

PROTEINS ARE BIG

For the first few years at NIH, I was primarily interested in studying complex small molecules such as natural products and peptides. When Laura Lerner joined my group she convinced me to add carbohydrates to the list. However, when in 1986 Michael Summers and I had completed a detailed NMR study of coenzyme B₁₂,²² primarily thanks to our development of the HMBC experiment, I had the feeling that methodologically this area might be maturing and my interests started to shift from small molecules to proteins. I had always avoided proteins like the plague, not in the least because I was horrified by the idea of staring into a light box for many months in a row. However, when Dennis Torchia, also at NIH, had managed to over-express and purify isotopically enriched staphylococcal nuclease, a protein of about 17 kD, he easily talked me into trying some of our small molecule experiments on nuclease. Together with Dennis and a very enthusiastic postdoc, Vladi Sklenar, we actually managed to get some neat experiments done. However, the big step came in 1988 when Dominique Marion and Lewis Kay decided they wanted to do 3D NMR. Dominique had joked that he ‘was tired of working on weekends’ and wanted an experiment that would run for at least three or four days. Unfortunately for him, a full disk on our old Nicolet spectrometer needed to be unloaded every 7 h or so, days, nights, . . . and weekends too. Right from the start it was obvious to us that heteronuclear 3D was the way to go and our first and successful attempt was to record a 3D ^{15}N -separated NOESY spectrum.²³

At that point it appeared to me that protein NMR might have a future after all and it was easy to convince NIH that investing in protein NMR would be a useful move. For starting a dynamic protein NMR program it would be essential to have a critical mass and we were fortunate to attract Marius Clore and Angela Gronenborn to the NMR program, which formed the beginning of a close and very productive collaboration. We also managed to obtain a significant commitment from NIH for space and capital equipment. With the arrival of two new AM-type Bruker spectrometers we were set to go and make serious attempts at recording high quality 3D spectra. The first hurdle that needed to be overcome, however, was the Bruker itself. In the normal mode of operation the ASPECT computer would require up to about 10 s at the completion of each increment to recompile the pulse sequence and get going again. Considering that most 3D experiments require only very few transients per increment, this compilation time more than doubled the duration of our 3-day 3D experiment, causing us some serious headaches. Fortunately, Rolf Tschudin, our electronics engineer, hired away by Ted Becker from Varian some 15 years earlier, was able to solve our problem by designing and building a box that would interrupt the Bruker pulse programmer clock for a defined amount of time that would increment each time the ‘Tschudin timer box’ received a clock pulse. This invention greatly reduced the time needed for recompilation of the pulse sequence and made 3D into a practical approach on the AM systems.

TRIPLE FUN

After our initial excitement about being able to record high-quality ^{15}N -separated NOESY and HOHAHA spectra, reality

sank in. Making complete resonance assignments based on these two types of 3D spectra was going to be a very long and tedious process. The protein calmodulin that my new postdoctoral associate Mitsu Ikura had just started to work on was probably the best possible example for illustrating how difficult it could still be to make the sequential assignment following the well-established Wüthrich procedure.²⁴ Because of the very high degree of α -helix in this protein, the amide and H^α chemical shift dispersion was particularly poor.

At that time, my colleague Dennis Torchia was exploring the possibilities for using several variations of the Kainosho double-labeling approach²⁵ for making sequential assignments. By selectively ^{13}C labeling a certain amino acid type, A, in the carbonyl position and another type of amino acid, B, with ^{15}N in the amide position, only B-type amino acids that are immediately preceded by an A-type residue show a $^1J(\text{N},\text{C})$ splitting in a ^1H – ^{15}N shift correlation spectrum. However, complete backbone assignment with this double-labeling approach required a large number of sample preparations and therefore a lot of work.

Dennis had the foresight to order a triple resonance probehead for his system; one that was optimized for proton detection but that also had a larger doubly tuned $^{13}\text{C}/^{15}\text{N}$ coil. I remember it took quite some effort to convince Bruker that this ‘crazy’ probe was what we wanted. With the capability to record 3D spectra already available, it was a relatively small step to come up with the so-called HNCO 3D experiment. This experiment ideally requires uniformly $^{13}\text{C}/^{15}\text{N}$ -enriched protein, so every backbone amide ^{15}N is preceded by a ^{13}C carbonyl and generates a spectrum where every backbone amide proton gives rise to a single resonance, with ^1H , ^{15}N , and ^{13}CO shifts determining the position of the resonance in the F_3 , F_2 , and F_1 dimension. The ^{13}CO shift itself is not very informative, but by conducting a second 3D experiment (HCACO) that correlates H^α , C^α , and the ^{13}CO shifts we argued it should be possible to correlate H^α/C^α of one residue with the $^{15}\text{N}/^1\text{H}$ resonances of the next residue, as both would connect to the same ^{13}CO chemical shift. Again we were fortunate to have Rolf Tschudin in our lab who was able to build very rapidly a third rf channel that we could control from the Bruker pulse program and actually try out these ‘Gedanken experiments’.

Primarily due to the creativity and persistence of Lewis Kay, we were finally able to make the triple resonance experiments work, and using the new 3D data Mitsu Ikura was able to complete his backbone calmodulin assignments shortly thereafter. Of course, we were tremendously impressed by our own accomplishments and were anticipating rave reviews when we submitted our results to the journal *Biochemistry*. To the contrary, the paper²⁶ was initially rejected. Such ‘complicated experiments’ requiring the very expensive ^{13}C labeling were deemed to be of no practical interest!

The next step in our structural study of calmodulin required making the side-chain assignments of calmodulin. Unfortunately, the presence of ^{13}C needed to disperse the ^1H – ^1H correlations into a third dimension also causes severe broadening of the ^1H resonances due to the strong ^1H – ^{13}C dipolar interaction. Regular ^1H – ^1H COSY approaches therefore were not expected to yield useful data for proteins the size of calmodulin and larger. Instead, we chose the same solution as for the backbone assignments: transfer magnetization

from one proton to another via one-bond heteronuclear J couplings, from ^1H to attached ^{13}C via $^1J(\text{C},\text{H})$, from ^{13}C to a second ^{13}C via $^1J(\text{C},\text{C})$, and back to the ^1H attached to this second ^{13}C . Despite the fact that magnetization in this so-called HCCH approach is transferred by three steps instead of one, such experiments are very efficient because each of the three steps transfers via a coupling that is larger than the pertinent linewidth.²⁷ Independent of our work Stephen Fesik, Erik Zuiderweg, and co-workers came up with an analogous solution which relied on isotropic mixing of ^{13}C magnetization with a MLEV17 scheme.²⁸ Both approaches are currently widely used.

Staring at all his ^{13}C assignments, Mitsu noted that there appeared to be a correlation between C^α chemical shift and the protein backbone conformation: all $^{13}\text{C}^\alpha$ carbons in α -helical residues showed a downfield shift relative to their random coil position. A subsequent more systematic analysis of the C^α and C^β shifts in four different proteins by Silvia Spera clearly demonstrated the generality of Mitsu’s observation.²⁹

WE CAN COUNT TO FOUR

In the same way as the idea of 3D NMR had been circulating for a long time before its real use was actually demonstrated, extending the dimensionality of the NMR spectrum to four was an obvious step to make. However, rather than proving that we indeed could count to four, we were looking for an application that would demonstrate its use. It was clear that spectral crowding is most pronounced in NOESY spectra and initially we wanted to focus on $^{13}\text{C}/^{13}\text{C}$ separated ^1H – ^1H NOESY, an experiment that later would prove to be extremely challenging.^{30,31} Instead, Marius Clore had a better idea that was much easier to implement: separate the ^{15}N -separated 3D NOESY into a fourth dimension, ^{13}C . This could be done with a minimal amount of phase cycling and Lewis Kay was able to obtain an impressive 4D spectrum for Marius’s interleukin-1 β .³² Subsequent attempts to obtain a high quality $^{13}\text{C}/^{13}\text{C}$ -separated NOESY spectrum proved that this was far more difficult and although we finally did manage to obtain such a spectrum only after the introduction of pulsed field gradients has this experiment become routine.³³

The performance of many of the triple resonance experiments was significantly improved by Stephan Grzesiek when we were trying to study the protein interferon- γ , which with a total molecular weight of over 31 kD presented a formidable challenge to our methods. Short T_2 values were ‘killing’ a number of the triple resonance experiments. By departing from our old dogma that ‘a good pulse sequence must have few pulses’, Stephan was able to improve dramatically the performance of many of them.³ The concept of ‘constant time’ was reintroduced, allowing dephasing and frequency encoding to occur simultaneously instead of sequentially, and with a few additional pulses Stephan also minimized the time that magnetization would be in the fast-relaxing antiphase state. Stephan also introduced a number of experiments that J -correlate the amino acid side-chain resonances with the backbone amides which made it possible for him to simplify dramatically the assignment process and complete the interferon- γ backbone assignments.³⁴

In the fall of 1991 Geerten Vuister, a graduate student of Robert Kaptein, joined my lab. Among other experiments, he

developed a large number of ingenious schemes for measuring homonuclear and heteronuclear coupling constants, most of them based on the concept of what we refer to as 'quantitative J correlation'. In this approach, the experiment is designed in such a way that, for example, the intensity of a cross peak between nuclei A and B is directly related to their J coupling. This turns out to be very practical and widely applicable in protein NMR. For example, not only was Geerten able to use this approach for measuring J couplings between amide and H^α protons, which characterize the backbone angle ϕ , but he was also able to measure $^3J(N,C)$ couplings between side-chain $^{13}C^\gamma$ and backbone ^{15}N .³⁵ This latter coupling turned out to be very small, ~ 2.2 Hz for *trans* and ~ 0.5 Hz for *gauche*. Even in small molecules it had previously been difficult to measure such couplings, whereas with this new method we are now able to measure these values in proteins as large as 20 kD. Together with $^3J(C,C)$, $^{363}J(C,N)$ defines the important χ_1 side-chain torsion angles and also aids in distinguishing the prochiral methyl groups in valine residues.

WHAT'S IN THE CRYSTAL BALL?

The introduction of stable isotopes in proteins by ourselves and others has extended tremendously the power of NMR for characterizing their structure. I anticipate that with further software development for automated assignment and for the analysis of the 4D NOESY spectra, determining a high-resolution structure for proteins up to a few hundred amino acids will become as routine as it is presently in crystallography. Undoubtedly, however, NMR will find increasing use in characterizing the dynamic features of a protein, which frequently are critical to its function and which may not easily be studied by other methods. The study of the dynamics of the linker region in calmodulin, carried out by Nino Barbato using the methodology that Lewis, Dennis, and I had developed earlier,³⁷ is an interesting example of such a study. In the crystalline state, the linker was found to be a rigid helix, giving the protein a dumbbell shape. In solution, at 35 °C and at physiological pH and salt concentration, five residues in the middle of the linker were clearly highly flexible as judged by their ^{15}N relaxation properties. Analysis of the relaxation rates for the amides in the small globular domains of the protein showed that these domains were subject to nearly isotropic rotational diffusion, in contrast to what would be expected for a rigid dumbbell.³⁸

Thus, it came as no surprise when subsequently Ikura, with the help of Marius Clore and Angela Gronenborn, was able to show that upon binding to its target the two globular domains come together with the target clamped in between them.³⁹

Present work is focusing on extending the size limit of proteins that can be studied by NMR by further improving the methodology. So far we have relied almost exclusively on ^{15}N and ^{13}C although it is clear that deuteration can also be tremendously useful.⁴⁰ An initial attempt by Stephan Grzesiek to combine both approaches showed encouraging results and yielded substantial line narrowing of the deuterated C^α carbons.⁴¹ A large number of different types of approaches along similar lines can be envisaged and only time, and lots of experiments, will tell which ones will be of long-term value.

The prospects for protein NMR are roesy, equipment is no longer inadequate and there remains plenty of room for further development of crazed ideas.⁴²

Biographical Sketch

Ad Bax. b 1956. Ph.D., Applied Physics, Delft University of Technology. Postdoctoral work at Colorado State University (on solid state NMR with Gary Maciel). National Institutes of Health, 1983–present, currently Chief of Biophysical NMR Spectroscopy Section, 230 publications. Current research specialty: biomolecular NMR.

Becker, Edwin D.: NMR at the NIH: Inception and Growth Over Four Decades

Edwin D. Becker

National Institutes of Health, Bethesda, MD, USA

I never planned to go into NMR, it just happened! As a graduate student in chemistry at the University of California at Berkeley in the early 1950s, I was working with George Pimentel in infrared spectroscopy. My Ph.D. thesis was largely devoted to testing a new method, ‘matrix isolation’ which permitted us to obtain infrared spectra of unstable molecules such as free radicals in a matrix of an inert solid material deposited from the gas phase (e.g. nitrogen or argon).¹ We also found the method useful for studying some aspects of hydrogen bonding,² a subject that I have pursued for many years, as I will describe.

MY FIRST INKLINGS OF NMR

During that period, none of this had anything to do with NMR (though matrix isolation came to be used in NMR studies many years later.) In fact, I don’t think I had ever heard of NMR until 1954 when Felix Bloch gave a talk at Berkeley. As I recall, he talked about relaxation, motional narrowing, and his recently discovered method of sample spinning. It would be nice to be able to say that that talk changed my research direction, but it didn’t. All this sounded like interesting physics, but it was not something that I could envisage for my own work. Later that year, Jim Shoolery gave a seminar at Berkeley and showed how Varian’s new ‘high-resolution NMR spectroscopy’ could be used to determine the structures of certain molecules. Now that seemed at least more relevant to chemistry, but the molecules he was able to study and analyze were very limited, and NMR seemed to me to be far from a really useful tool in chemistry. Nevertheless, some seeds must have been planted by these talks. I still remember them 40 years later even though they had no immediate impact on my perspectives.

One other event at Berkeley turned out to be very important in my eventual journey into NMR. One of George Pimentel’s other students, Charles Huggins, was studying the effect of hydrogen bonding on the frequency and intensity of infrared bands. George suggested (perhaps that’s not the right word!) that Charles look into the use of NMR in a collaboration with Jim Shoolery. Some very useful results came from that work,³ and I learned more about NMR from Huggins’ reports back at our lab.

ON TO NIH

After receiving my Ph.D. in 1955, I came to the National Institutes of Health for what I thought would be a two to three year postdoctoral stint. NIH turned out to be a marvelous place to do research, so I spent my entire career here. I originally came to NIH to work with Urner Liddel, a physicist who had done some fundamental studies of hydrogen bonding by infrared methods in the 1930s, then served as a science administrator in government and in industry before returning to lab research at NIH. We were doing infrared studies, but both Urner and our Section Chief, Fred Brackett (who had discovered Brackett’s Series in the spectrum of atomic hydrogen in 1922) were interested in the potential of NMR. In the fall of 1956 that interest, together with my slight acquaintance with Shoolery and the hydrogen-bonding work, led to my being sent for a week to Palo Alto to work with Shoolery and evaluate the potential of NMR for chemical analysis, but especially for hydrogen-bonding studies.

LIDDEL AND RAMSEY

Let me provide a sidelight here about Urner Liddel. He really didn’t know much about NMR, but he had published the first paper on the effect of hydrogen bonding in NMR. According to Urner’s account, that started one day in 1951 when Urner, then in the Office of Naval Research, visited Norman Ramsey’s lab at Harvard. Ramsey had the structure of ethanol on his blackboard and explained that he was puzzling over some results from Stanford that showed the chemical shift of the OH peak in ethanol to be markedly temperature-dependent, while the CH₃ and CH₂ chemical shifts were temperature-independent.⁴ Liddel commented that he had studied hydrogen bonding in ethanol many years earlier, and Ramsey inquired as to whether this hydrogen bonding would be temperature-dependent. Of course, replied Liddel, because of the equilibria involved, which would also be affected by diluting ethanol with a non-hydrogen-bonding solvent such as CCl₄. Liddel returned to his office in Washington, and not too long thereafter he received in the mail a manuscript, ‘Temperature Dependent Magnetic Shielding in Ethyl Alcohol’ by Liddel and Ramsey, which Ramsey had already sent to the *Journal of Chemical Physics*.⁵ The role of hydrogen bonding is put forth as a plausible explanation for the temperature dependence, and a test of the explanation is proposed: dilute the ethanol in CCl₄. Arnold and Packard did just that and reported their results on the same journal page along with the Liddel–Ramsey paper.⁶

Liddel’s second (and last) paper on NMR was my first—a quantitative study of hydrogen bonding in ethanol that I carried out with Jim Shoolery during that week at Varian in 1956.⁷ We did a few other experiments as well, and my report to the NIH hierarchy on the potential for NMR was sufficient for our institute to purchase a 40 MHz spectrometer. I still continued to be more interested in vibrational spectroscopy than in NMR, but when the NMR instrument arrived in the summer of 1957 I was considered the local expert. After all, I had had a week at Varian, and that was 1 week’s more experience than anyone else at NIH! I often regret never having had any formal training

in NMR, but sometimes one can manage just by plunging in. So I was put in charge of the new acquisition, which at \$30 000 was our most expensive instrument. Ever since, I have divided my research time between vibrational spectroscopy and NMR, but with increasing emphasis on NMR as the field developed spectacularly.

EARLY NMR STUDIES

Most of my initial work in NMR was related to structure elucidation. It was marvelous to have an NMR spectrometer at that time. Organic chemists came to see whether 'that big machine' would tell them what compound they had isolated or synthesized. Sometimes it did! I was glad to help other investigators with their work, and I obtained access to a number of compounds that I could use to study more fundamental aspects of NMR. In the late 1950s many NMR spectroscopists had studied steroids, alkaloids, sugars, amino acids, peptides, and other classes of molecules, but no one had reported on porphyrins. Because of their importance in heme proteins, chlorophyll, and other important substances, I thought that we should investigate the NMR spectra of some simple, metal-free porphyrins. Several biochemists at NIH worked with porphyrins and seemed willing to provide samples. The problem was the quantity needed. When I said 10 mg would be adequate, there was usually a pause, then a statement, 'You must mean 10 μ g'. No biochemist could believe the quantities we needed for NMR, but remember this was during the days of 60 MHz spectrometers and long before time averaging. In 1959 I finally found an adequate source of porphyrins: Cecil Watson, an expert in internal medicine at the University of Minnesota, had long studied the disease porphyria and had developed a strain of cows that excreted large amounts of porphyrins. He could (barely) provide the 10 mg samples needed. My associate Bob Bradley and I ran spectra of several of these compounds and published the first NMR papers on porphyrins.^{8,9} By far the most surprising observation, as shown in Figure 1, was the position of the NH resonance, which was about 4 ppm *more* shielded than tetramethylsilane — one of the very few such 'high field' resonances that had ever been detected. The

reason, of course, is that these protons lie *inside* the porphyrin ring, and the large ring current shields them, just as we should have expected on the basis of the Johnson–Bovey picture of π -electron circulation.¹⁰

Hydrogen bonding continued to be one of my interests. In the 1960s I began to delve into the effect of H-bonding on the chemical shift of the hydrogen acceptor. Oxygen was not easy to study but ^{15}N offered some possibilities. We used and modified double resonance methods to allow us to study ^{15}N chemical shifts in enriched compounds with the sensitivity of ^1H , an essential requirement for the dilute solutions that we had to use for such studies.¹¹ Nowadays, of course, such studies can be carried out with ^{15}N in natural abundance by various inverse detection methods, but in the pre-Fourier transform days such techniques were beyond comprehension. Much later, with better methods, we made studies of chemical shifts¹² of ^{17}O and the effect of H-bonding on ^{13}C relaxation times.^{13,14}

HIGHER FIELDS AND LARGER MOLECULES

Of course, we have upgraded NMR instruments over the years, with the initial 40 MHz to 60 MHz improvement coming only a year or two after our initial purchase. I think I made one important decision in the early 1960s *not* to follow the crowd in moving to 100 MHz. High homogeneity superconducting magnets were clearly on the horizon, so I preferred to conserve our financial resources and obtain one of the early 220 MHz instruments and later a 270 MHz spectrometer. For almost a decade we had the only superconducting NMR systems in the southeastern part of the country. Not only did they permit many investigators at NIH to make rapid advances in chemical and biochemical research, but we were able to provide instrument time to many people outside the NIH.

Todd Miles and others at NIH introduced me to problems in the structure and hydrogen-bonding interactions in nucleosides and nucleotides. We showed that the Watson–Crick base pairing is dominant for mononucleosides,¹⁵ found the site of protonation in a number of cytosine derivatives,¹⁶ and measured internal rotation in cytosine derivatives.^{17,18} Tom Pinnavaia came from Michigan State University to spend his sabbatical in my lab in 1974–75. He discovered that guanosine-5'-phosphate (GMP) in neutral or basic solution self-associates by hydrogen bonding to give a stable structure in which the H-bonds exchange only slowly on the NMR timescale. We were able to interpret the NMR, along with ancillary infrared spectral data, in terms of an unexpected tetrameric structure (**1**).¹⁹ We noticed a large 'hole' in the center which should tend to destabilize the structure, but Tom, an inorganic chemist, realized that a counterion such as Na^+ would fit neatly into the hole. In fact, as later shown by Cherie Fisk's study of GMP by ^1H and ^{13}C NMR, the structure is an octamer consisting of two stacked planes bound together by the Na^+ .²⁰ Today the guanosine tetramer of Figure 2 is of great interest in the mechanism of chromosome replication.

Figure 1 ^1H NMR spectrum (60 MHz) of coproporphyrin-1 methyl ester in CDCl_3 (0.05 M). M = CH_3 ; P = $\text{CH}_2\text{CH}_2\text{COOCH}_3$. The peak at $\delta + 3.89$ ppm is due to the NH protons. Note the old sign convention for denoting chemical shifts which is opposite to currently accepted practice.

FARRAR AND BECKER

During the 1960s I had the good fortune to meet Tom Farrar, who was then at the nearby National Bureau of Standards.

Figure 2 Tetrameric structure formed by self-association of GMP.

Tom was building pulse NMR apparatus and was interested in possible chemical applications. We began collaborations initially aimed at studies of rate phenomena, but this was soon bypassed by the idea of using Tom's pulse spectrometer to excite ^{13}C free induction decays that could be Fourier-transformed to yield spectra in a reasonable time. The first such spectra were obtained only with great difficulty, paralleling the cumbersome procedures used a few years earlier by Ernst and Anderson in their pioneering work on Fourier transform NMR of protons. Jim Ferretti, who was then in the Division of Computer Research and Technology at NIH, played a key role in taking data from Tom's lab on paper tape, bringing the tape to NIH, where one computer converted it to punched cards (!), which could then be fed into a second computer to do the Fourier transform. Such niceties as phase correction required an inordinate amount of further hands-on computation. But we did get ^{13}C spectra and eventually built better pulse spectrometers that could be interfaced to the then new minicomputers, such as the Nicolet 1080. Meanwhile, Gitte Shoup (later Vold), Tom, and I studied ^{13}C relaxation and clarified the relative importance of various relaxation mechanisms.²¹ During this period I also thought up a pulse method for restoring magnetization to its equilibrium value more rapidly than T_1 processes and expected it to be useful for studying ^{13}C NMR. At my insistence that we provide a catchy acronym, Tom and I came up with the name Driven Equilibrium Fourier Transform.²² The acronym DEFT had a very positive connotation. Unfortunately DEFT turned out not to be useful for ^{13}C studies²³ but many years later has found some applicability in NMR imaging. Soon after publishing, we were embarrassed to find that we had simply reinvented a pulse sequence reported eight years earlier by Streever and Carr in their paper on relaxation of ^{129}Xe .²⁴ I'm not sure whether to be pleased or dismayed that our acronym served as the basis for a plethora of acronyms for really useful techniques, e.g. WEFT, SEFT, and, especially, INEPT.

The collaboration with Tom certainly ranks as one of the high points in my NMR career. In addition to our research, we decided to organize a course at the NIH Graduate School on the then new pulse NMR methods, and that in turn led to our book

Pulse and Fourier Transform NMR.²⁵ We decided to limit this book to a simple introduction that would be comprehensible to chemists and wrote it in six months. We persuaded the publisher (for whom I had already written a successful book on High Resolution NMR,²⁶) to rush the book out in six months and to charge no more than \$7.50, since we wanted it to be widely used. After 20 years this book still sells a few copies per year (at a now absolutely exorbitant price!). Its success probably stems largely from the fact that Tom and I were both feeling our way along with these methods that were then quite foreign to chemists, and our explanations were understandable because we were almost explaining it to ourselves.

FURTHER EVOLUTION OF NMR AT NIH

For me the 1970s was an exciting period, highlighted by continuing developments in Fourier transform methodology. We worked largely at optimizing pulse methods so they would be useful in practical applications.²⁷ Raj Gupta spent a year at NIH and spearheaded several investigations into the efficiency of measurements of relaxation times^{28,29} and especially the practical development of the rapid scan correlation method³⁰ that had been devised by Dadok and Sprecher.³¹ This method is still in use as an inexpensive alternative to pulse FT in 60 MHz instruments designed for analytical studies.

While I spent most of the 1980s dealing with administrative matters as an NIH associate director, I maintained contact with NMR. Fortunately we recruited Ad Bax, essentially as my successor, and his accomplishments are legendary. Soon we were able to bring Marius Clore and Angela Gronenborn to our lab to start a program on protein NMR studies. Meanwhile, in the 1970s Dennis Torchia had joined NIH, and we agreed to cooperate in sharing equipment and facilities. This combination of outstanding NMR investigators, together with excellent financial support, has made NIH a world-class facility for NMR studies of protein structure. Although NIH is organized into many small, independent research groups, we have always had excellent cooperation from all the NMR spectroscopists in maintaining an atmosphere that is conducive to collaboration and sharing of both instruments and ideas.

I have also been able to observe closely the advent of NMR imaging and in vivo spectroscopy, even though I have had only limited participation in these areas.³² I remember a meeting in New York in late 1972, when Paul Lauterbur told me during an evening stroll about his first imaging experiments (published a few months later). Like many great ideas the concept seemed in retrospect almost obvious, but it was clear from the beginning that this technique would be of great importance. I followed developments in Paul's lab and elsewhere very closely and in 1977 was able to facilitate David Hoult's joining NIH to take up research in imaging. Later, in the 1980s, when imaging and in vivo spectroscopy were firmly established worldwide, I was fortunately able to combine my background in NMR with my broader administrative functions to organize the NIH In Vivo NMR Research Center, where scientists from many different labs at NIH are able to share equipment and facilities, and moreover to exchange ideas in developing and applying these fascinating techniques. We were able to recruit top-notch talent (e.g. Chrit Moonen and Jeff Alger) to join with other NIH investigators, such as Bob

Balaban, Jack Cohen, Andy Byrd, Bill Egan, and David Hoult, to establish the Center.

A FINAL NOTE

Editing this volume of the Encyclopedia is a real pleasure, especially since I have had the opportunity to be in close touch with the early (and not so early) giants in the development of NMR. For someone that never intended to go into NMR, I have found it a very rewarding career.

National Institutes of Health, 1955–present; Laboratory Chief (1972–80, 1988–present); Associate Director for Research Services (1980–88). Concurrent position on Faculty, Georgetown University, 1959–present. Books on NMR. Research interests and publications: hydrogen bonding, molecular structure elucidation, technique development in NMR and other areas of molecular spectroscopy.

Béné, Georges-J.: The Early Days of NMR Research in Geneva

Georges- J. Béné

Section de Physique, DPMC, Geneva, Switzerland

INTRODUCTION

A series of fortuitous events led the present author in the autumn of 1947 to take up research in a field which was entirely new in continental Europe, namely nuclear magnetic resonance.

I had completed several months beforehand my preparatory work at the University of Lyon for a Doctorat ès Sciences when serious family reasons prompted me to apply for a scholarship offered by the University of Geneva to a doctoral student from Lyon. My candidature was successful and on 30 October 1947 Jean Weigle, then the Director of the Institut de Physique at the University of Geneva, assigned the first tasks that were to lead to a doctorate. They involved the comparison of magnetic resonance frequencies of nuclei when the magnetic field B_0 is produced by an electromagnet with ferromagnetic pole pieces and by an ironless coil in order to reveal a pure spin–spin interaction—if it existed—between the moments of the pole pieces and those of the sample's atoms as proposed by Stueckelberg.¹

I should perhaps point out that Jean Weigle on returning from a short stay in the USA had brought back the very first publications of E. M. Purcell, F. Bloch, and their co-workers. This collection was complemented in 1948 by the famous article of N. Bloembergen, E. M. Purcell, and R. V. Pound on nuclear relaxation.

FIRST NMR DETECTION

Work started immediately with this (limited) material. The small team headed by Dr. R. C. Extermann as the project leader (he was to succeed J. Weigle as Professor and Director at the Institut de Physique) included P. Denis, another doctoral candidate who joined us several months later.

It is unnecessary to recall our difficulties in getting the research moving: the construction of an oscillator; tests of various types of bridges including that of Purcell; modifications of an old electromagnet whose homogeneity left much to be desired; the winding of crossed coils for a Bloch spectrometer. The equipment was finally almost complete at the end of June 1948 . . . , but there was still no proton signal.

By participating at the international conference 'Spectroscopy at Radiofrequencies' of the Physical Society held in Oxford at the end of July, my colleague R. Extermann and I were able to come into contact with the main exponents in the field present at the conference (Bloembergen, Rollin, Drain . . .). Above all, however, we found out many details from Drain on how his spectrometer worked. The entire team set to

work assiduously when we returned to Geneva, and on the 14 August 1948 we observed the proton signal in a dilute solution of ferric nitrate using Bloch's method at a frequency of $\nu_0 = 10$ MHz.

I was informed at this time that without adequate replenishment my scholarship dried up at the end of July 1948. G. Déjardin, my former 'patron' in Lyon who had been responsible for my finding a scholarship, worked extremely efficiently in helping me obtain support from the French CNRS, starting in October 1948.

On the scientific level, the observed resonance signal was made unusable by transients of various sorts; our first task was to identify and analyze all of them.

TOWARDS THE EARTH'S MAGNETIC FIELD

In order to detect the Stueckelberg effect, two conditions had to be fulfilled. One was the use of an ironless coil to generate the magnetic field. Ours, which had been made available by our colleagues at the University of Lausanne, comprised two coils in a Helmholtz configuration capable of being cooled with circulating water. With this we were able to observe the proton resonance at $\nu_0 \simeq 3$ MHz although stability problems obliged us to work at field strengths below 3.5×10^{-2} T. Resonances for ^1H and ^{19}F were thus detected at $\nu_0 \simeq 1.4$ MHz.

The Stueckelberg effect was not observed, but fortunately the Helmholtz coils permitted the inhomogeneity of the magnetic field at the center of symmetry to be calculated accurately for the analysis of transients. Our first publication, presented at the spring meeting of the Swiss Physical Society at Brienz on 7 May 1949, dealt with a thorough study of the 'beats' discovered and analyzed by Jacobsohn and Wangness.² That communication was made a few weeks before the first publication on NMR made by the group from the Ecole Normale Supérieure (ENS) in Paris (30 May 1949). The converging objectives of the two groups became the basis for a close and fruitful collaboration, the only engagement of this type in NMR in continental Europe at the time.

The study of the effects of the speed at the resonance of the sweep field led us to reduce the amplitude of the B_0 static field and increase that of the alternating sweep field. In February 1954 we observed proton resonance in a purely alternating field with a frequency of $\nu_0 = 350$ kHz. Unfortunately, the inhomogeneity of the B_0 field prevented the determination of the lineshapes or linewidths of the narrowest resonances. It was because of this that a proposal by Yves Rocard, then the Director of the Physics Laboratory at the ENS, attracted us. He offered technical assistance and financial support—provided we studied NMR in the Earth's magnetic field, B_T .

Collaboration with a doctoral student from Lausanne (Claude Manus) and with scientists from Paris (mainly J. Winter, B. Cagnac, and J. M. Rocard) allowed us in the spring of 1955 to observe proton resonance in the Earth's field. Our spectrometer was then set up in the middle of a forest where the proton linewidth in benzene did not exceed 1.5×10^{-10} T. Work carried out with this installation is described elsewhere in this Encyclopedia in a contribution entitled *Terrestrial Magnetic Field NMR* to which the reader can refer.

Successively Professeur Associé, Extraordinaire, Ordinaire, University of Geneva (CH) 1956–1989. President Physics Section of Geneva University 1969–1977. General Secretary (1956–1989) and President (1970–72) of the AMPERE Group—Member of the Steering Committee (1966–68) and of the Council (1968–89) of the European Physical Society. Retired (Honorary Professor) since 1989. Approx. 250 scientific publications.

Bertini, Ivano: A Life with Paramagnetic Molecules

Ivano Bertini

Department of Chemistry, University of Florence, Italy

I come from the School of Inorganic Chemistry of the late Luigi Sacconi. In the early 1960s he was in competition with the School of R. H. Holm at MIT who was pioneering NMR applications to paramagnetic nickel(II) complexes. I therefore went to ETH Zürich to perform my first ^1H NMR spectra of paramagnetic bis-salicylaldiminatonickel(II) complexes. The instrument was a Varian HR-60, with no lock and field sweep. The calibration was obtained through sidebands. I joined in 1966 the club associated with the high-resolution NMR of paramagnetic compounds in solution.¹ The first instrument purchased by the University of Florence in 1967 was a Varian DA 60, with internal lock and frequency sweep. We implemented the instrument with an audiofrequency generator in order to modulate the sweeping radiofrequency with the aim of achieving large spectral widths. In this way we could go beyond the 100 ppm spectral width, although highly shifted signals usually suffered from excessive line broadening. The problem of spectral width was, and is, quite serious in the investigation of paramagnetic molecules.

When the FT instruments became available, the most versatile for this kind of problem were the Bruker CXP and then the MSL instruments because of the high power, short 90° pulses, and short dead times. We could therefore afford to record the ^1H signals of high spin cobalt(II) proteins with a spectral width of 200 ppm and low concentration (≈ 1 mM) of the macromolecule. The first spectrum, partly assigned, of a cobalt protein was that of cobalt-substituted carbonic anhydrase (MW 30 000).² Among other systems, I can recollect liver alcohol dehydrogenase (MW 80 000) which shows the $\beta\text{-CH}_2$ signals of coordinated cysteines between 200 and 300 ppm downfield.³ Finally, we investigated a paramagnetic copper(II) protein (copper–zinc superoxide dismutase) by allowing copper to interact magnetically with cobalt through a bridging ligand. This is a uniquely successful example in which the electronic relaxation times of a metal ion (copper) have been changed with the aim of making a system suitable for NMR investigation.⁴

With the advent of 600 MHz instruments, it became clear (at least to me) that the magnetic field strength was the main quality of an instrument. Again, we faced the problem of the spectral width. Bruker had built for us a probe which could stand an unusually high power radiofrequency, featuring a proton 90° pulse of $3.5\ \mu\text{s}$, with little loss of signal-to-noise. With this probe and a fast ADC we were able to measure spectra over 300 ppm and to perform 2D NOESY spectra on the same spectral width.⁵

If the spectral width has been a limit to overcome, another is the development of time-dependent spin Hamiltonians and suitable software. The problems addressed have been the development of strategies for the suppression of strong signals (e.g. solvent) in order to reduce dynamic range drawbacks. Such drawbacks are particularly serious for paramagnetic molecules which readily display low intensity broad signals.

The most successful strategies for signal detection are those which exploit the different relaxation times. Hence NOE experiments were made feasible for fast relaxing nuclei thanks to improvements in spectrometer stability and to the optimization of pulse length, pulse phases, and pulse sequences. The latter have been developed to overcome artifacts which could be dramatic when fast relaxing signals are saturated or inverted.⁶ Finally, the optimization of parameters has made possible 2D and 3D spectra for paramagnetic molecules.

During the development of these techniques we found a novel manifestation of cross correlation.⁷ Nuclear relaxation in paramagnetic molecules may be due to the presence of a time-averaged electronic magnetic moment. The contribution due to nucleus–nucleus dipolar coupling may also be operative and the two mechanisms cross correlate. As a result, COSY spectra display cross peaks even in the absence of scalar coupling. Such cross peaks contain further structural information. We consider this to be a sign that the NMR of paramagnetic molecules has matured and deserves full recognition in the NMR community.

Simultaneously, I tried to understand further the effect of electron relaxation on nuclear parameters. I interacted in this area with S. H. Koenig formerly at IBM, Yorktown Heights, NY. I introduced zero-field splitting and hyperfine coupling with metal nuclei in the evaluation of nuclear relaxation. Finally, efforts were made to understand why magnetic coupled metal clusters may have such short electron relaxation times to be suitable for NMR characterization.⁸

I should also say that these achievements from the Florence laboratory were possible thanks to my former students, and now colleagues, Claudio Luchinat and Andrea Scozzafava and at a later stage to my pupil Lucia Banci. I am also indebted to Prof. W. DeW. Horrocks who has been one of my teachers.

Bible, Roy H. Jr.: NMR: An Organic Chemist's Dream Come True

Roy H. Bible, Jr.

G. D. Searle & Co., Skokie, IL, USA

My own interest in NMR as an analytical tool originated from my intense concern with the structures of organic molecules. I had worked at G. D. Searle & Co. as an organic chemist at the bench for 12 years before the first easily operated NMR instrument, the Varian A-60, became available in 1961. Prior to that time, we had only elemental analysis, UV, IR, and optical rotatory dispersion available as supplements to solubility tests, color reactions, and chemical derivatizations to assist us in the structure elucidation of molecules.

The first NMR spectrum which I received on a compound of my own was a 40 MHz proton spectrum determined at the Worcester Foundation for Experimental Biology and Medicine. At that time we were attempting to introduce a methyl group into a steroid, and were using the integration of the $7.25\ \mu\text{m}$ infrared absorption band to determine if we had, in fact, achieved our goal. The NMR spectrum immediately gave the answer, and the analytical world has never been the same since.

From the organic chemist's viewpoint, the availability of the Varian A-60 spectrometer revolutionized NMR. Suddenly spectra were easily obtained and plotted on a precalibrated chart rather than on the strip recorder with markings generated by an audio signal generator. The field and frequency were locked together by use of an internal water sample. I first saw the A-60 in a hotel room in Chicago during an ACS meeting, where it was being demonstrated by NMR pioneers LeRoy F. Johnson and James N. Shoolery of Varian Associates.

My interest in the structure elucidation of organic compounds had already led me to become a consultant of sorts at G. D. Searle in the interpretation of IR and UV spectra. The availability of a Varian A-60 instrument at Searle rapidly led to my full-time involvement in the use of physical techniques for the elucidation of structures. Because the older techniques were primarily chemical, the new techniques were called 'physical methods' and in 1966 I became 'Head of Physical Methodology'.

My first exposure to a collection of proton spectra was an examination of the proof copy of the first Varian catalog by Shoolery, Bhacca, and Johnson, at one of the early Varian Workshops in Palo Alto, CA. I studied the spectra intensely, trying to relate the spectral characteristics to the structures. I recall that my traveling companions were on edge while I studied the spectra, because we were running late to catch a plane back to Chicago. Perhaps this pattern of my trying to gather the last bit of data before leaving the laboratory for a lecture or a trip still persists.

For my own mental enjoyment, I find it necessary to correlate all the small pieces of data into a larger picture. On arrival of our A-60 at Searle, I presented a seminar which summarized the major aspects of the interpretation of proton NMR data. To make the seminar as useful as possible, I assembled the discussion into a small spiral-bound pamphlet,

which resulted in my being asked to give similar talks for various outside groups.

Charles Bell and Ludwig Bauer had decided that there was enough interest for a short course in NMR at the University of Illinois School of Pharmacy, and invited me to give a presentation there. My little booklet evolved further, and eventually I was the lead-off speaker at the short courses at the School of Pharmacy. In the 1-hour presentations I told everything I knew about the interpretation of proton spectra! The presentation expanded as my own knowledge base grew and, at the last short course, included a reasonable discussion of second-order effects in proton spectra.

I remember distinctly at one of the School of Pharmacy sessions that LeRoy Johnson had an HR-100 spectrometer. The magnet was powered by enormous vacuum tubes which glowed white-hot and generated a tremendous amount of heat.

Herman A. Szymanski heard me present my 1-hour summary of the interpretation of proton spectra, and had seen the booklet which I had prepared. He suggested that I write a book on the interpretation of proton spectra. I eagerly accepted his suggestion, and the book was published by Plenum Press in 1965.

As an organic chemist, I wanted to know how to use NMR. The theory was of interest to me, but the important thing was the use of NMR data to determine the structures of organic molecules. To make the contents of my book very clear, I entitled it *The Interpretation of NMR Spectra—An Empirical Approach*.

This small book was followed by a work-book which led the organic chemist by the hand through the interpretation of specific examples of NMR spectra. Both books were translated into Japanese. The first book was also translated into Russian, without permission of course. Surprisingly, both of these books were still being sold at a very moderate rate even in 1993.

I still believe that most of the use of NMR comes from an empirical application of observations rather than from the application of theory. Attesting to this, I think that there are very few practising NMR spectroscopists who really understand the Cooley–Tukey fast Fourier transform algorithm and its implementation in the computer.

In 1966, Varian, with the cooperation of the American Chemical Society, sponsored a short course in NMR at Pittsburgh airport. This location was, in fact, a center of operations for Varian. They had both an applications laboratory and a parts depot. There was a legendary service engineer, Cappy Joller, who, according to legend, had memorized all the schematics and critical voltage measurements and could recite the details on the spot.

The course taught at the Pittsburgh airport, which included the hands-on use of instruments, was led by LeRoy F. Johnson. In 1967, LeRoy Johnson asked me if I would be willing to help teach an ACS course on the interpretation of proton NMR spectra. He said that the empirical approach which I had taken in my book appealed to many of the participants. Thus began my teaching partnership with LeRoy Johnson, which has continued over the years and still actively goes on.

The course which we taught on the interpretation of proton spectra changed every time we taught it of course, and naturally I learned more from teaching it than the participants learned from taking the course. From our experience, we published an ACS audio course in 1978. We incorporated every advancement that came along, and at every course we would

show the spectra which we had obtained from the latest NMR instrumentation.

My teaching with LeRoy Johnson led to my involvement in other short courses: a series at Canisius College which was started by Herman Szymanski; a series at the University of New Hampshire organized by Robert E. Lyle; a series organized by John Grutzner of Purdue University; and currently a series originated by Harry C. Dorn and taught at Virginia Tech.

The Experimental NMR Conferences have played an important role in my own NMR education. George Slomp of Upjohn and I always sat in the front row and made audio tapes of nearly every talk. I remember Richard Ernst's presentation of his first Fourier transform experiments, and Paul Lauterbur showing images of an earthworm which he chose as a sample because it fitted in his 5-mm tube. I remember the detailed discussions by Castellano and Bothner-By on computer simulations of spin-spin coupling patterns and determinations of coupling constants to a hundredth of a hertz.

My own excitement in NMR has come from the tremendous amount of information made available to the organic chemist

about how his molecule of interest is put together and how it behaves. My interests have been on the practical side, always eager to use theory where it would help to solve a problem, but in general emphasizing the most practical techniques which could be used to solve chemical and structural problems with the least effort. To one who initially had to integrate peaks by first tracing them on paper, then cutting them out and weighing the paper, it is very rewarding to see how NMR has evolved. I am sure that the fun and excitement have just begun!

Biographical Sketch

Roy H. Bible, Jr. b 1926. B.S., 1948, Virginia Tech., M.S., 1949, Ph.D., 1951, University of Illinois at Urbana. Successively medicinal chemist, Head of Physical Methodology, Assistant Director of Analytical Resources and Methods, Director of Physical Methodology, research fellow, and currently senior research fellow and Director of Physical Methodology. Two NMR texts and, with LeRoy Johnson, an ACS sponsored audio course on the interpretation of NMR spectra. Lecturer in many short courses. Research specialty: application of NMR techniques in organic chemistry, especially in structure determination.

Blinc, Robert: The AMPERE Society and the Development of Magnetic Resonance in Eastern Europe

Robert Blinc

University of Ljubljana, Ljubljana, Slovenia

Despite the fact that electron spin resonance had already been discovered in the radiofrequency region in 1944 in St. Petersburg by Zavoisky (and the corresponding article published in German in the *Phys. Zeitschrift der Sowjet Union*) the development of magnetic resonance in Eastern Europe—and also in most of Western Europe with the exception of Great Britain—was significantly slower than in the United States. This was the result of the destruction during the World War II, the emigration of a significant part of the European scientific elite to the USA before and after the war and the ‘iron curtain’ which was dividing Europe into two parts: western Europe which was slowly recovering with the help of the Marshall plan, and eastern Europe where, among other things, the dictatorial regimes imposed severe restrictions on the free exchange of goods, scientists, and scientific information. To stimulate magnetic resonance research in Europe and to overcome the general lack of equipment, literature, know-how, and many other resources in the field of radiospectroscopy, R. Freymann from Paris at a conference in Oxford in 1948 proposed the idea of creating a liaison bulletin to exchange information and to ask for government support to purchase surplus American equipment for joint use. With the help of Professors Alfred Kastler (who later won the Nobel Prize), Yves Rocard, and Pierre Grivet, Freymann’s idea gained support and in 1952 the first AMPERE (= Atomes et Molécules par Etudes Radio-Electriques) conference was held in Paris. In 1953 the first issue of the Bulletin AMPERE was published by George Béné from Geneva. The AMPERE group was created as an association of scientists and laboratories, not of official national organizations—with a minimum of bureaucratic constraints. It was first a society of French speaking radiospectroscopists but the frontiers became more and more open at each subsequent meeting and in 1955 most magnetic resonance laboratories in western Europe participated. One of the important goals of the AMPERE group was to promote scientific contacts between scientists in eastern and western Europe in spite of all the political difficulties. In order to facilitate these contacts, Geneva in neutral Switzerland was chosen as the seat of the secretariat.

In Great Britain, Oxford and the British Radiospectroscopy Group were centers of excellence in magnetic resonance research with Professors Bleaney, Andrew, and Jack Powles. Professor Abragam from France had also been a prominent visitor to Oxford. In the Netherlands, France, Italy, and Belgium, magnetic resonance groups were working successfully. In East Germany, A. Lösche had started magnetic resonance research and had written the book *Kerninduktion*. In Switzerland, magnetic resonance centers in Geneva—Béné, Peter—and in Zürich—Känzig, Gränicher—had been established. In West Germany, Karl Hausser was essential in building up magnetic resonance research and H. Dehmelt—who later left for the USA—discovered nuclear quadrupole resonance (some years later he won the Nobel Prize for his measurements of the g -factor of the electron). Professor Laukien started the Bruker company. In the Soviet Union, the center of magnetic resonance research had moved to Kazan with Professor Altschüller, whereas important low-temperature work had been done by Borovik-Romanov in Moscow. Much later a very successful center was established in Estonia by Lippmaa. Magnetic resonance groups were also starting in Poland in Poznan and Krakow, in Romania in Cluj (Ursu) and in Zagreb and Ljubljana in Yugoslavia (at present in Croatia and Slovenia).

In 1956 the first scientist from eastern Europe, Professor A. Lösche from Leipzig, was invited to attend the Colloque AMPERE in Geneva and in 1961 the AMPERE Congress was held in Leipzig, i.e. in the same year as the Berlin Wall was built. In 1965, a year before the Congress AMPERE in Ljubljana, the AMPERE Society had already 550 member physicists from 12 western and eight eastern European countries. In 1972, at the AMPERE Summer School in Baško Polje on the Adriatic coast which was organized by the Ljubljana group, Jean Jeener first proposed the idea of 2D NMR. A student from Switzerland informed his advisor Richard Ernst about Jeener’s proposal, resulting in the development of multidimensional NMR. John Waugh, Erwin Hahn, and many other scientists from the USA also took part at this event. They, as well as Alex Pines, became regular guests at subsequent AMPERE events, much to the benefit of the development of magnetic resonance in eastern and western Europe.

Biographical Sketch

Robert Blinc. b 1933. Ph.D., 1959, Physics, University of Ljubljana. Postdoctoral work with J. S. Waugh, MIT, Cambridge, MA. Faculty member (currently Professor of Physics), University of Ljubljana, J. Stefan Institute, 1969–present. President of AMPERE Society 1988–94. Approx. 450 publications and, with B. Žekš, the book ‘Soft Modes in Ferroelectrics and Antiferroelectrics’; ISMAR prize, 1977. Research interests include NMR of phase transitions and disordered condensed matter.

Bloch, Felix: The Principle of Nuclear Induction

Felix Bloch

Nobel Lecture, December 11, 1952

© Le Prix Nobel, 1952

It is a tribute to the inherent harmony and the organic growth of our branch of science that every advance in physics is largely due to the developments that preceded it. The discovery for which Purcell and I have received the honor of the Nobel Prize award for the year 1952 is a typical example of this situation, and before describing the principle I shall therefore present an outline of its long and distinguished background.

Both the method and the object go back ultimately to spectroscopy, a field to which modern physics owes so much in other respects. Among the various aspects of this field there are two which are of particular importance here: the Zeeman effect for introducing magnetic fields as an essential element of spectroscopy, and the hyperfine structure of spectral lines for revealing the existence of nuclear moments. The correct interpretation of hyperfine structures was first given in 1924 by Pauli,¹ who proposed that atomic nuclei may possess an intrinsic angular momentum (spin) and, parallel to its orientation, a magnetic moment. The energy of interaction of this magnetic moment with the magnetic field $H(O)$, produced by the atomic electrons at the position of the nucleus, depends upon the angle between them and leads thus to the observed small splitting of the energy levels. Conversely, it is possible under suitable conditions to determine from this splitting both the spin and the magnetic moment of the nucleus, and these two important quantities have indeed been determined in a great number of cases from the observation of hyperfine structures. The magnetic moments of the nuclei have been found, in all observed cases, to be of the order of the 'nuclear magneton' which one obtains by substituting in the formula for the atomic Bohr magneton the mass of the proton in place of that of the electron. Nuclear moments are thus about a thousand times smaller than atomic moments, and this is plausible in view of the fact that one deals here with protons instead of electrons as elementary charged constituents. There are, however, distinct disadvantages in the optical determination of nuclear moments. In the first place the accuracy is seriously limited due to the fact that the effect consists only in such a small splitting of spectral lines that one has to be concerned with their finite width. In the second place it is necessary for the determination of the nuclear magnetic moment from the observed hyperfine structure to have a knowledge of the field $H(O)$ which is usually rather inaccurate since it involves complex electron configurations. In view of these limitations one is led to values of nuclear magnetic moments with an accuracy of a few per cent at best. Finally, one is faced with the fact that hyperfine splittings tend to decrease with decreasing atomic number with the result that it is not possible, by optical means, to observe them in the case of the greatest fundamental importance, that of hydrogen.

A decisive step forward was made in 1933 by Stern,² who applied his method of molecular beams to the determination of the magnetic moments of the proton and the deuteron in hydrogen molecules. Instead of the emitted light, it is here the deflection of the molecule in an inhomogeneous magnetic field which is affected by the nuclear moments. Although the observed effect was close to the limit of observability it yielded the proton moment to within 10% with the most important result that instead of having the expected value of one nuclear magneton it is about 2.5 times larger. Of similar importance was the result that the magnetic moment of the deuteron was between 0.5 and one nuclear magneton, since it indicated from the simplest plausible considerations of the structure of this nucleus that one should ascribe a moment of about 2 nuclear magnetons to the neutron. I shall come back later to this point; it represents the start from which my own experimental work has followed in an almost continuous line.

Subsequent to Stern's work, a number of far-reaching further developments have been achieved by Rabi in the application of atomic and molecular beams to the measurement of nuclear moments and hyperfine structures. Without attempting completeness I want to mention some aspects of method in the brilliant series of investigations which he carried out with his collaborators. One of them is based upon a paper by Breit and Rabi,³ which treats the variation of the magnetic moment of an atom for the different Zeeman levels of hyperfine structure under the influence of an external magnetic field and which was applied to atomic beams where the deflection gives a direct measure of the magnetic moment. Another important aspect lies in the passage of the beam through two and later three separate field regions which can be adjusted to give zero deflection so that one deals with a null method. These innovations, besides giving many other interesting results, allowed the measurement of the hyperfine structure in the ground state of light and heavy hydrogen atoms; since the previously mentioned field $H(O)$, produced by the electron at the place of the nucleus, was given here, through a formula of Fermi⁴ from the well-known theory of the hydrogen atom, this measurement resulted in the determination of the magnetic moments of the proton and the deuteron with an accuracy of a few per cent.

However, the most significant improvement in molecular and atomic beam techniques was the introduction of the magnetic resonance method. The beam here passes through a region where the magnetic field is homogeneous and constant with a weak alternating magnetic field superimposed at right angles to the strong constant field. Analogous to the resonance absorption of visible light, transitions occur here from one Zeeman level to another if the alternating field satisfies Bohr's frequency condition for the energy difference between the two levels. However, instead of optical frequencies one deals here normally with frequencies in the radio range so that this application of the magnetic resonance method, like our own, is properly labeled as belonging to the new field of radiofrequency spectroscopy. In the beam technique it has the great advantage of dispensing with a knowledge of the deflecting inhomogeneous fields, since the deflection is merely used now as an indicator for the occurrence of transitions in the homogeneous field region. A very much greater accuracy can thus be obtained; it led, for example, to the knowledge of the magnetic moments of the proton and the deuteron with an accuracy of about one part in a thousand and to the important

Figure 1 The 'head' of the crossed coil arrangement with the cover plate removed. The bottom tube to the right contains the leads to the transmitter coil, which is wound in two sections visible in black in the head. The black cable leads from the receiver coil to the amplifier; the receiver coil is wound with a vertical axis inside the hollow lucite piece between the two sections of the transmitter coil. The sample test tubes are placed in its interior through the circular hole at the top of the supporting frame

discovery of a small but finite electrical quadrupole moment of the deuteron⁵ in 1939.

The first use of the magnetic resonance method was suggested in 1936 by Gorter⁶ in an attempt to detect the resonance absorption of radio quanta through the heating of a crystal. While the results of this experiment were negative, Rabi⁷ in 1937 has treated the transitions in a rotating field and has pointed out their use in atomic and molecular beams.

Coming from quite a different direction, I was led at that time to similar ideas. They originated from my preceding work which dealt with the magnetic moment of the neutron and which had been stimulated by Stern's previously mentioned measurement of the magnetic moment of the deuteron.² The idea that a neutral elementary particle should possess an intrinsic magnetic moment had a particular fascination to me, since it was in such striking contrast to the then only existing theory of an intrinsic moment which had been given by Dirac⁸ for the electron. Combining relativistic and quantum effects, he had shown that the magnetic moment of the electron was a direct consequence of its charge and it was clear that the magnetic moment of the neutron would have to have an entirely different origin. It seemed important to furnish a direct experimental proof for the existence of a magnetic moment of the free neutron, and I pointed out in 1936⁹ that such a proof could be obtained by observing the scattering of slow neutrons in iron. The very strongly inhomogeneous magnetic field in the neighborhood of each iron atom was shown to affect a passing neutron through its magnetic moment and thus to lead to an appreciable magnetic scattering effect; it was shown at the same time, that magnetic scattering would lead to the polarization of neutron beams. The existence of this effect was first clearly demonstrated in 1937 by a group of investigators at Columbia University,¹⁰ and it opened up the possibility of further work with polarized neutron beams.

The most desirable goal to be reached here was that of accurately measuring the magnetic moment of the neutron. It occurred to me that resonance depolarization could be achieved by passing a polarized neutron beam through a region where a weak oscillating field is superimposed on a strong constant field, provided that the frequency of the former is equal to the frequency with which the neutron moment carries out a precessional motion around the direction of the constant field. A knowledge of this field and of the corresponding resonance frequency directly determines the magnetic moment under the safe assumption that the spin of the neutron is $\frac{1}{2}$, and the magnetic scattering effect enters in this arrangement merely as an indicator for the occurrence of resonance depolarization. The application to polarized neutron beams was also noted by Rabi⁷ in his previously mentioned original paper on the magnetic resonance method. It was first achieved in 1939 by Alvarez and myself¹¹ with the use of the Berkeley cyclotron, and yielded a value for the magnetic moment of the neutron which was consistent with that of the deuteron if one assumed the latter to be additively composed of the moments of the proton and the neutron. The accuracy of this measurement amounted to about 1% and was partly limited by that with which the strength of the constant field could be determined. Another limit of accuracy arose from the smallness of the observed polarization effect, but a subsequent systematic investigation of neutron polarization,¹² carried out with the Stanford cyclotron, showed how this effect could be greatly increased.

Figure 2 The same head as in 1, about to be inserted in the gap of an electromagnet and containing a sample test tube. The two protruding lucite rods between the leads reach into the interior of the head and carry small copper disks; a fine adjustment of the coupling is achieved by rotation of these 'paddles'

Figure 3 A resonance line of protons in water, containing MnSO_4 as a paramagnetic catalyst, and obtained from the phase component of the nuclear induction signal which corresponds to absorption. The photograph is that of the trace on a cathode-ray oscillograph with the vertical deflection arising from the rectified and amplified signal and the horizontal deflection corresponding to different values of the constant field

It was of considerable importance to improve the accuracy of the determination of the neutron moment to at least one part in a thousand in order to test small deviations from the additivity of the moments of the proton and the neutron, which could be expected in connection with the finite electric quadrupole moment of the deuteron, according to the theoretical work of Rarita and Schwinger.¹³ The fact that higher accuracy hinged essentially upon that of a field calibration and the search for a suitable and convenient standard led me to new ideas when, toward the end of the last war, my thoughts turned back to the continuation of my previous work.

The essential fact of the magnetic resonance consists in the change of orientation of nuclear moments, and the methods to be employed in molecular and atomic beams as well as in neutron beams are primarily indicated by the different ways to detect this change. The acquaintance with radio techniques during the war suggested to me still another and much simpler way, that of detecting the reorientation of nuclear moments through the normal methods of radio reception. The signals to be detected would be due to the electromagnetic induction caused by nuclear reorientation and should appear as a voltage difference between the terminals of an external electric circuit. I believe that this is the most general and distinctive feature of our discovery, and it is for this reason that I chose for it the name of 'nuclear induction'. Purcell, whose independent approach was largely based on considerations of energy relations, has chosen to call it 'nuclear magnetic resonance absorption', but soon after our respective initial work and despite its apparent difference, it became clear that it was based upon the same principle.

In order to understand this principle, one can start from macroscopic quantities and describe the underlying phenomenon in classical terms. Consider for this purpose, as a typical example, about one cubic centimeter of water with the protons contained in it as the nuclei under investigation.

Their magnetic moments are oriented in a completely random manner in the absence of an external magnetic field; after the sample has been brought into such a field, however, there will be established a new thermal equilibrium in which the magnetic moments are distributed with a slight surplus parallel to the field. Even in relatively strong fields of the order of 10 000 G this surplus will at room temperature amount to no more than about one part in a million. While its direct observation would be difficult, there thus exists a 'nuclear paramagnetism' in the sense that one deals with a finite macroscopic nuclear polarization which is both parallel and proportional to the applied external field. The establishment of thermal equilibrium demands the transfer of the energy released by the partial orientation of the nuclear moments into heat, and it can take place only through interaction of these moments with their molecular surroundings. The strength of this interaction determines the time interval required for the nuclear moments to adjust themselves to the equilibrium conditions; it is measured by the 'relaxation time', as in the analogous case of atomic paramagnetism. The role of the relaxation time is of basic significance for our experiments, and I shall soon come back to its discussion.

For the moment, we shall return to the equilibrium state, once it is established, and to the description of the nuclear polarization under the conditions of magnetic resonance. A simple mechanical consideration of the gyroscope shows that an alternating field at right angles to the constant field has the effect of tilting the direction of the polarization with respect to the constant field and that the polarization will

Figure 4 The only difference between this line and that of Figure 3 lies in the adjustment of the observed phase which is here that corresponding to dispersion

thereupon continue to perform a precessional rotation around this field. The angular frequency of precession is proportional to the field with a constant of proportionality which is called the 'gyromagnetic ratio' of the nuclei and which is equal to the ratio of their magnetic moment and their intrinsic angular momentum. From a perfectly macroscopic point of view, one thus deals with a situation in which the protons in our cubic centimeter of water have the effect of an invisible compass needle rotating in its interior. The 'invisibility' refers actually only to observation of optical frequencies; the rotation occurs in the range of radiofrequencies, and it can very well be observed by using Faraday's law of induction. Indeed, the rotation of our compass needle is accompanied by that of a magnetic field which possesses an alternating component perpendicular to the axis of rotation, and hence by an electromotive force, induced in a suitably wound coil of wire around the sample. From here on it is merely a matter of the standard techniques of radio reception to rectify and amplify this electromotive force so that it can be recorded on a voltmeter, displayed on a cathode-ray oscillograph, or made audible in a loudspeaker.

What amazed me most in my first calculations on this effect was the magnitude of the signals which one could expect from nuclear induction. In our example of a cubic centimeter of water in a normal field of a few thousand gauss they turned out to amount to the order of a millivolt. This magnitude is well above the noise which accompanies any radio receiver and which sets the ultimate limit of signal detection. It should be observed here that, being a phenomenon of fluctuations, the noise can always be reduced by averaging over sufficiently long times. This procedure was used later to very greatly increase the sensitivity of the method; it is characteristic of the present possibilities that my collaborators have succeeded in the last few years in detecting in natural water signals arising from deuterium and from the isotope of oxygen with atomic mass 17, despite their low abundances of 0.02% and 0.04%, respectively.

The existence and detection of a precessing nuclear polarization in a sample represents to my mind the basis of nuclear induction. It is, however, necessary to consider also the features which produce and counteract the tilt of the polarization with respect to the constant field. Magnetic resonance enters here as the most important means of producing the tilt, since it allows its achievement under the application of relatively weak oscillating fields. In fact, it is a common feature of every resonance phenomenon that relatively weak external forces can produce large effects if their frequency is equal to the natural frequency of the system to which they are applied. The natural frequency in question is, in our case, that with which the nuclear polarization precesses by itself around the constant field and the practical way to determine this frequency is to vary either that of the applied alternating field or the magnitude of the constant field until resonance conditions are established and detected by a maximum of the observed nuclear induction signal. The simultaneous knowledge of resonance field and frequency then directly yields, as in the use of magnetic resonance in molecular beams, the gyromagnetic ratio and, with a knowledge of the spin, the magnetic moment of the nucleus. Actually, it is also possible to determine the spin separately by using the additional piece of information contained in the intensity of the observed signal.

To follow the analogue of mechanical resonance we must now come back to relaxation, which can be seen to act like a friction, and which counteracts the tilt produced by the alternating field. If the friction is large, i.e., if the relaxation time is short, it will either reduce the effect for a given amplitude or require a correspondingly larger amplitude of the alternating field. It will, in either case, result in a relatively broad resonance line, thus diminishing the accuracy of the measurement. While from this point of view it is undesirable to have too short a relaxation time, it is equally undesirable to have it too long, since the very circumstance of producing its tilt diminishes the magnitude of the polarization so that it requires the refreshing influence of the relaxation mechanism to bring it back to its equilibrium value.

There was not much known about the magnitude of nuclear relaxation times when Purcell and I started our first experiments on nuclear induction, and the main doubt about their success arose from the possibility of insufficient relaxation. In fact, it seems, in retrospect, that the failure of Gorter's first attempt,⁶ as well as of a second one, undertaken in 1942,¹⁴ was primarily due to this circumstance. While E. M. Purcell, H. C. Torrey, and R. V. Pound,¹⁵ toward the end of 1945, obtained their first positive results from protons in paraffin, the late W. W. Hansen, M. E. Packard, and I¹⁶ found ours a few weeks later in water without either of the groups knowing anything about the work of the other. The relaxation time of paraffin has the convenient value of about 1/100 s, while pure water has a somewhat unfavorably long relaxation time of about 2 s. Neither of these two values had been foreseen, and I was fully prepared to find the relaxation time of pure water considerably longer and in fact too long for our method of observation. It was known, however, that the conversion of *ortho*- and *para*-hydrogen was accelerated by the presence of paramagnetic atoms and molecules; this mechanism has the common feature, with the attainment of the equilibrium polarization of protons, that it requires a random process of nuclear reorientation, and it had been understood to take place through the magnetic field of the paramagnetic catalyst acting upon the magnetic moment of the proton. An estimate showed that, depending upon the concentration of a paramagnetic salt dissolved in water, a wide range of relaxation times, going down to values of the order of 10^{-5} s, could be obtained. Before starting our observations we therefore had prepared solutions of the paramagnetic iron nitrate in water, and although the first weak signals were received from pure water we found, shortly afterward, considerably stronger signals from a solution with about 0.5 molar concentration of iron nitrate. The signals appeared as rather broad lines on the cathode-ray oscillograph because of insufficient homogeneity of the constant magnetic field.

Since the width of the resonance line determines the accuracy with which magnetic moments can be determined, we shall briefly consider the conditions necessary for obtaining sharp lines. In the first place, it is necessary that the constant field have the same value in all parts of the sample; in the second place, one must not choose an excessive amplitude of the alternating field, since this too would cause an excessive broadening. The ultimate limit is given by the natural width of the line and it is closely related to the relaxation time; it can be seen, in fact, that the relative accuracy of a measurement by nuclear induction, due to the natural linewidth, is limited to the

order of the number of cycles which the nuclear polarization carries out in its precession around the constant field during the relaxation time. As an example, we shall again consider protons in pure water and in a field of 10 000 G; the frequency of precession is here 42.5 Mc/s, so that about 10^8 cycles are performed during the relaxation time of approximately 2 s. This means that an accuracy of about 1 part in 100 millions could be, in principle, achieved here, provided that one had a sufficiently homogeneous field available. While this limit has not yet been reached, it is noteworthy that in water, alcohol, and other liquids, resolutions of one part in 10 millions have actually been achieved. It is indeed the possibility of coherent observation over a large number of cycles which allows the use of nuclear induction as a method of high precision measurements. In fulfillment of my original plans, it was applied by H. H. Staub, D. B. Nicodemus, and me to the magnetic moments of the proton, the neutron and the deuteron,¹⁷ and it resulted not only in the verification of the previously mentioned deviation from additivity in the deuteron,¹³ but in its measurement with an accuracy which is beyond the present scope of the theory of nuclear forces. It was particularly gratifying to me to obtain these results from experiments combining the polarization and magnetic resonance depolarization of neutrons with nuclear induction.

The description of nuclear induction which I have presented follows closely my own original thoughts on the subject but it can equally well be approached from other angles. The simplest one is probably that of Gorter⁶ in his first attempt to detect nuclear magnetic resonance. We have seen before that the alternating field tilts the nuclear polarization against the constant field. This process requires a certain amount of work which, through relaxation, will reappear in the form of heat produced in the sample. The effect in fact does not involve induction but represents pure nuclear resonance absorption; however, it would be very slight and has not yet been established. A second attempt of Gorter,¹⁴ carried out later, is based upon the fact that the nuclear paramagnetic susceptibility has a maximum for radiofrequencies, corresponding to magnetic resonance conditions; it would manifest itself in the frequency of an electric oscillator of which a coil, surrounding the sample, forms the self-inductance. This scheme is actually one of the many others which can be devised for the observation of nuclear induction and, if successful, would have represented the first demonstration of the effect. Purcell's first successful experiment involved the electro-dynamical aspect of absorption insofar as its occurrence under resonance conditions was manifested through the increased loss of a cavity resonator; the cavity was replaced in his succeeding arrangements by more conventional circuit elements. A particularly suitable and convenient arrangement consists of a radiofrequency bridge, which contains in one arm a coil, surrounding the sample. As a consequence of nuclear induction there occurs, under resonance conditions, a change of the impedance of this coil and thereby a readily detectable change in the balance of the bridge. It should be remarked that the change of impedance is complex, with its real part corresponding to absorption, its imaginary part to dispersion. This fact can be traced back to the phase relation between the nuclear induction signal and the applied radiofrequency field, and the phase sensitivity of the bridge allows the observation of the effect either as absorption or as dispersion or as a combination of both.

Finally, I shall give a brief description of our own original arrangement which we still use in its principal features. The essential balance which Purcell has obtained by a bridge method is here to a large extent achieved geometrically by using two radiofrequency coils with their axes oriented at right angles to each other and to the constant field. One of them, the 'transmitter coil' produces the alternating field, while the other, the 'receiver coil', serves for detection of the nuclear induction signal (see Figures 1, 2). A small amount of coupling between the two coils is admitted to produce a voltage across the receiver coil, and its phase with respect to the superimposed voltage induced by the nuclei can be adjusted for the observation of either absorption or dispersion in similarity to the bridge method (see Figures 3, 4).

A considerable variety of other circuits has been introduced by different investigators. Except for the greater or lesser ease of avoiding instrumental difficulties, they lead to the same ultimate sensitivity and accuracy of the method, since they all observe the same basic phenomenon.

There is, however, one distinctive feature in the cross-coil arrangement, which automatically yields another significant piece of information. The two coils imply a sense of rotation around the constant field; depending upon whether the nuclear polarization precesses in the same or the opposite sense of rotation there results a phase difference of 180° between the voltage in the receiver coil due to coupling with the transmitter coil and the superimposed voltage due to nuclear induction. The action of the rectifier translates this phase difference into an inversion of the signal, which is directly displayed on the oscillograph or on the recording instrument. One obtains in this simple manner information about the sign of the magnetic moment of the nucleus, defined by its relative orientation to the angular momentum, since it is this sign which determines the sense of rotation of the nuclear polarization in a given field. The sign of nuclear moments represents an important clue to their interpretation in terms of nuclear structures; usually it is referred to the sign of the proton moment, which has been known for a considerable time to be positive. It has been determined in this manner for a number of nuclei where it was not previously known.

Bloembergen, Nicolaas: My Early Years in NMR, 1946–48

Nicolaas Bloembergen

Pierce Hall,, Harvard University, Cambridge, MA, USA

I had the good fortune to arrive at Harvard University in February 1946, about six weeks after the discovery of nuclear magnetic resonance in condensed matter by Edward M. Purcell, Robert V. Pound, and Henry C. Torrey.¹ This volume contains a first-hand account of the facts surrounding this discovery written by Pound (*Pound, Robert V.: Early Days in NMR*).² He begins by describing the concentrated activity of scientists at the MIT Radiation Laboratory to advance radar techniques which played a vital role in the conduct of World War II.

I passed those war years in The Netherlands, occupied by Nazi forces. I studied physics at the University of Utrecht and passed my qualifying doctoral examination in April 1943 just a few weeks before the German authorities closed all Dutch universities. I survived the remaining two war years without significant scientific activity.

After the liberation of The Netherlands in May 1945 by the allied forces, the prospects for carrying out good physics research in Europe to obtain a Ph.D. degree in a reasonable time were dim. I therefore wrote to three universities in the United States, which I identified on the basis that the *Physical Review* in the years prior to 1942 had published a substantial number of papers originating from these institutions. Only Harvard University responded positively to my inquiry. The formalities of documentation required for admission to the Graduate School of Arts and Sciences, for a Dutch passport, for a US student visa, for a permit to exchange Dutch to US valuta, and obtaining passage on a liberty ship freighter from the destroyed port of Rotterdam to the United States took about eight months. My arrival at Harvard in the middle of February 1946 was determined by these external factors, but it turned out that I had arrived at a propitious place at a propitious time.

The contrast between the anemic state of academic affairs in the war-torn Netherlands and the exhilarating pulse of scientific research in Cambridge, Massachusetts, was bewildering at first, but members of the Harvard physics faculty were most helpful and sympathetic. I discussed the possibility of cosmic ray research with Professor J. C. Street and of NMR research with Professor E. M. Purcell. The latter topic appealed to me more, because it was a new experimental technique and it was somewhat related to Dutch work on magnetic relaxation which I had heard about. More important was the fact that Professor Purcell needed a pair of hands for a follow-up on the pioneering experiment,¹ while he, Pound, and Torrey were still engaged in writing chapters for the MIT Radiation Laboratory Series. The spring term 1946 at Harvard had an exceptionally large and gifted class of graduate students. Most of them had just returned from military service, had no previous laboratory experience, and were enrolled in a full-time course program. Fortunately I had brought with me a preprint of predoctoral research work

carried out at the University of Utrecht.³ It involved the development of a low-noise photoelectric amplifier coupled to a phase-sensitive a.c. galvanometer.³ On this basis Purcell accepted me tentatively as his first graduate student and as a quarter-time laboratory assistant. He advised me that I should also take two graduate courses. I enrolled several weeks late in a course on electromagnetism given by Julian Schwinger and a course on statistical mechanics by E. C. Kemble. Since I had taken both subjects before with L. Rosenfeld in Utrecht, I had no trouble with either course and spent most of my time in the laboratory.

My first task was to make a mud pie of mineral oil and calcium fluoride powder and to stuff it through a small coupling hole into the cavity used in the first NMR experiment. A few days later I witnessed the detection of both the proton and fluorine NMR signals, as Pound controlled the electronic equipment and Purcell managed the magnet current.

My next task was to build a lock-in amplifier according to Dicke's design.⁴ It would take many years before this item would become commercially available. I familiarized myself with RCA vacuum tubes, electronic components, chassis punches, etc. My craftsmanship was marginal. The lock-in performed reasonably during my 18 months at Harvard, but was relegated to the scrap heap soon after my departure. I also built a 30 Hz multivibrator oscillator and power amplifier to feed the modulation coils installed on the 1905 electromagnet from the Société Générale, which was to serve us in future experiments. The ponderous cavity was replaced by an LC circuit resonant near 30 MHz. The coil was placed in a shielded sidearm which fitted into the 1-in. wide gap between the pole pieces of about 5 in. diameter. The Q -value of the LC circuit was about one order of magnitude smaller than that of the cavity, and the sample volume was reduced by three orders of magnitude. The coil was about 1 cm long with a 0.5 cm inside diameter.

The stability of the magnetic field caused problems, because of low-frequency variations in the output of an old dc generator with a wobbly armature. I spent considerable time building a feedback amplifier to stabilize the current. This effort was not successful and it was decided to supply the magnet current from truck storage batteries. A jury-rigged rheostat consisting of clamp sliding along manganin strips adjusted the current. The research budget was extremely limited and 'string and sealing wax' techniques were widely used.

When I. I. Rabi visited Harvard in April 1946, balancing the radiofrequency bridge was still a tricky art. Purcell was disappointed that we were not able to show Rabi the proton NMR signal in water or mineral oil on the lock-in output meter. After they left, I tuned all controls from scratch and within an hour or so was able to get the signal back. I rushed upstairs to Purcell's office. Fortunately Rabi was still there and they were both happy to see the NMR signal.

I built a more symmetrical rf bridge with orthogonal adjustments of amplitude and phase, so that the in-phase and out-of-phase part of the nuclear magnetic susceptibility could be measured independently. We observed saturation of the NMR resonance when the rf power was turned up, while increasing the balance of the bridge so as to keep the input to the rf amplifier at a constant level.

At this time Purcell and Pound had returned from the MIT Radiation Laboratory and could devote more time to the project. When I once mentioned to Bob Pound that the

signal appeared to change in magnitude after reinsertion of the probe in the magnet gap, he immediately moved the probe around the gap in a systematic manner. We found the narrowest resonance with the largest peak signal at the location away from the center of the gap near the edge of a pole piece. This was caused by inhomogeneities in the magnet material. The minimum linewidth in water and some other fluid samples was about 0.14 G. At this 'sweet spot' of minimum inhomogeneity of the magnetic field, the resonance in a CaF_2 sample remained broad.

We decided we could measure the true width, proportional to T_2^{-1} , in a single crystal of CaF_2 . We also realized that this width should show a marked anisotropy and would be a minimum when the magnetic field was pointed along the body diagonal of the cubic lattice. In this orientation the nearest neighbors would not contribute a static local field component parallel to the external field. It is the magic angle δ between the body diagonal and the cubic axis, for which $3 \cos^2 \delta = 1$. I spent a few days cutting a cylinder with its axis along a face diagonal out of a natural CaF_2 crystal. This cylindrical sample could be rotated inside the rf coil. Our observed linewidths were in agreement with a formula for the second moment of internal dipolar fields derived by Van Vleck. Purcell spent hours on a Marchant mechanical calculator to evaluate the dipolar lattice sums for a cubic lattice. This resulted in a joint publication with Purcell and Pound.⁵

Of more interest were the narrow lines in fluids. We realized that we could not measure their true width which was masked by the magnetic field inhomogeneity but we could measure the relaxation time T_1 . Somehow the motion in the fluids 'averaged out' the local magnetic field variations produced by neighboring nuclear spins. Very soon the term 'motional narrowing' was coined, as the three of us moved our index fingers relative to one another in space to visualize the time dependence of dipolar interactions. The variations of the local field with time were the important clue to magnetic relaxation problems.

Purcell and Pound conceived an experiment on hydrogen gas. The local field, and therefore the Larmor precession frequency, would change during the collisions. The collision rate could be varied by changing the pressure. Pound² describes how he understood the process of averaging as a rapid random modulation of the resonant frequency. They built a cell which contained an rf coil and hydrogen gas at a variable pressure. It was found the relaxation time T_1 increased as the pressure was increased from 10 atm to 30 atm. The term 'pressure narrowing' was introduced, even though the magnetic field inhomogeneity prevented direct observation of the true width.⁶ This behavior stands in sharp contrast to the 'pressure broadening' familiar in optical spectroscopy.

I concentrated my attention on the proper description of the time-dependent local field in liquids. Fortunately I had followed a seminar on Brownian motion and noise given by J. M. W. Milatz in 1942 at Utrecht. I had written the lecture notes for it which had been distributed in mimeographed form. I was therefore familiar with the concept of power spectral densities of random variables. Purcell made the valuable suggestion that the book by Debye entitled 'Polar Molecules' would be relevant.⁷ He was obviously aware of the high frequency dielectric losses of polar liquids. The dielectric relaxation in polar liquids is caused by the random rotation of the electric dipole moments as described by Debye. During the fall of

1946 I worked out the spectral density of the various terms in the dipole-dipole interaction between two proton spins due to the random rotation of a water molecule. I also calculated the contributions to the local field spectral density of translational Brownian motion of spins in different molecules. I realized that the Fourier components in the local field at the Larmor frequency and twice the Larmor frequency were responsible for the longitudinal relaxation process and determined T_1 . I remember I obtained explicit equations for T_1 in water between Christmas 1946 and New Year in my dormitory room, when a bad cold prevented me from going to the lab.

The transverse relaxation process described by T_2 also had a contribution from Fourier components near zero frequency. I correctly surmised that a self-consistent description required that motional narrowing starts when the local field spectral density has a correlation time shorter than T_2 for the static case. It need not be short compared to the resonant period.

These insights could of course be tested by varying the viscosity of the fluid samples. I prepared scores of samples with hydrocarbons from light to heavy oils, water-glycerin mixtures, and measured their viscosities. The experimental data for T_1 for these samples fitted the theory nicely.

All this experimental and theoretical activity took place during the last three months of 1946. During this period I evolved from a lab assistant to a full-fledged research partner. Purcell decided that I should present the results on NMR relaxation in liquids at the annual meeting of the American Physical Society in New York City in January 1947. The abstract was published in the *Physical Review*.⁸ My mandate was to get the essential ideas of T_1 in fluids across in 10 min. Thanks to a rehearsal at Harvard before a critical audience consisting solely of Purcell and Pound, I was able to finish the presentation in accented English before a packed audience at Columbia University a few seconds before the chairman's bell rang.

The spring of 1947 was spent in rounding out the experimental data for my Ph.D. thesis. I realized that the cleanest way to check the dependence of T_1 on the correlation time τ_c of the fluid motion was to vary the temperature of a glycerin sample over a wide temperature range. At -40°C glycerin is almost glasslike. I soldered some copper tubing around the brass pipe containing the rf coil and put a can filled with acetone and dry ice above the magnet gap. I started a syphoning action by sucking some cold acetone which then dripped into another can below the magnet gap. The temperature of the sample was monitored with a thermocouple. Thus the smell of acetone was added to the acrid smell from the overnight battery recharging process in the basement room of the Lyman laboratory. Environmental regulations did not impede the pace of progress in NMR research in early 1947. I also realized that many solids including ice had sufficient internal motion to explain observed relaxation times T_1 . The shortening of T_1 by paramagnetic ions in solution was quantitatively measured. A few additional experiments on the relaxation of ^{19}F and ^7Li in ionic solutions were also carried out.

I made the inhomogeneous broadening of the linewidth in water visible on the screen of an oscilloscope in the following way. I first turned off the current in the modulation coils. The rf field would then saturate the protons in that part of the sample where the resonance condition was satisfied. I next turned up the modulation current to a large value so as to sweep through

the whole resonance broadened by the field inhomogeneity. This resonance showed the saturation dip. I called it 'eating a hole out of the inhomogeneous distribution'. The dip filled up in a time of a few seconds. I was so excited by this observation made during a weekend that I immediately called Purcell at his home. A few days later we filmed the disappearance of the 'hole' with an 8-mm movie camera and determined that $T_1 = 2.3$ s in water. Of course, we also checked that the resonance in CaF_2 was homogeneously saturated and showed no dip.

I built another rf bridge at 4.8 MHz to extend the T_1 measurements to a lower frequency. The theoretical dependence of T_1 on $\omega\tau_c$ was verified. The lower frequency also permitted the detection of the deuteron magnetic resonance in heavy water with the magnet at our disposal. In a 50:50 per cent mixture of light and heavy water, I found the relaxation time of D to be much shorter than that of H . I realized that the explanation should be found in terms of a time-dependent quadrupolar interaction, and I subsequently calculated the spectral density of the electric field gradient explicitly. This observation of the relaxation time in heavy water is an early manifestation of a nuclear quadrupole interaction in condensed matter.

While Purcell and Pound were regular participants in the experiments in the fall of 1946, their visits to the basement room in 1947 became infrequent. Pound had shifted his interest to the study of nuclear quadrupole interactions in solids, while Purcell was not only busy with teaching duties but also with preparing other research projects for additional graduate students. Already in 1946 he had designed a permanent magnet with a field of about 6000 Oe in a gap of about 2 cm. George Pake used this magnet to study the lineshape of NMR in a gypsum crystal. Pake worked in the basement room next door to mine and we conversed regularly through a hole in the wall. We decided to move the permanent magnet to the physics lecture hall to give a public demonstration of NMR at the Harvard Physics Colloquium in April 1947 where I had been invited to speak. By this time the experimental work for my thesis was essentially complete.

Professor C. J. Gorter from the University of Leiden was a guest lecturer at Harvard arriving in the summer of 1947. He gave a special course on paramagnetic relaxation based on his book written during the last years of the war.⁹ I had not met him before in The Netherlands. He was of course much interested in the work on magnetism carried out at Harvard by J. H. Van Vleck and by Purcell's group. I explained to him that I would like to submit my Ph.D. thesis with him at Leiden, since I had already passed all my qualifying examinations in The Netherlands and I did not want to spend the time and money to repeat them at Harvard. Gorter was enthusiastic and immediately offered me a research position at Kamerlingh Onnes laboratory in Leiden. I was to start there in September 1947. Purcell was quite understanding and agreed to this arrangement. He and Van Vleck, who was then Chairman of the Physics Department, were however interested in my eventual return to Harvard. They arranged for me to be interviewed by the Senior Fellows of the Society of Fellows before my departure. I was to hear in 1948 in The Netherlands about the outcome of this interview.

I witnessed discussions between Gorter and Van Vleck about the influence of scalar spin exchange interactions in electron paramagnetic resonance. Gorter argued correctly that the rapid spin flip-flop exchanges would cause the equivalence of motional narrowing. This viewpoint appealed to me.

Van Vleck argued, also correctly, that the scalar exchange interaction leaves the second moment of the resonance line invariant. He subsequently realized that the exchange interaction greatly enhances the fourth moment and that consequently the observed resonance would indeed exhibit exchange narrowing.¹⁵

During the summer of 1947 I completed the rough draft for my thesis which I discussed with Gorter and Purcell. The latter retained a copy of my handwritten notes which would serve as the basis for the comprehensive paper we planned to publish in the *Physical Review*.¹⁰ It was also decided to communicate the essence of our results more quickly in a note in *Nature*.¹¹ This decision was probably spurred by the appearance in this journal of some related work by B. V. Rollin and others¹²⁻¹⁴ at Oxford University.

Gorter and I were both keen on introducing NMR techniques to the European continent and extend the relaxation investigation to liquid helium temperatures. We decided that we could make a quick start by duplicating the Harvard setup. We therefore went to the Boston Radio Shack and bought all the electronic equipment and components needed. The Kamerlingh Onnes lab had of course good electromagnets and cryostats. I had the NMR setup going within one month after my arrival in Leiden. The machine shops there were supervised by highly professional master technicians and instrument makers. It was not appreciated, or even permitted, for scientists to do an amateurish job as I had done at Harvard. If one went through the established channels, however, beautiful gadgets were delivered on a surprisingly fast schedule. The liquefaction of hydrogen and helium was entirely in the hands of the technicians and no mortal scientist was allowed to touch a helium Dewar. Liquid helium was only available on Thursdays and my low-temperature experiments had to be scheduled well in advance.

Gorter, who was busy as Director of the large Kamerlingh Onnes Laboratory, left me complete freedom to proceed as I wished. I was most interested in understanding the NMR relaxation mechanism in solids without large-scale atomic motion. I knew that Waller's theory on the interaction of nuclear spins with phonons predicted extremely long relaxation times,¹⁶ and I had confirmed this by calculating the change in local fields produced by the classical motion of vibrating atoms. Clearly paramagnetic impurities might play a role. They would have to produce local fields at the nuclear Larmor precession frequency and it occurred to me that the z component of the electron spin might produce such Fourier components, as it executed random transitions through the interaction with lattice vibrations in the paramagnetic relaxation process. For a quantitative test a series of potassium aluminum crystallites were grown, doped with concentrations of Fe^{3+} ions varying from a few ppm to a few per cent. The relaxation time in these samples was measured from room temperature to liquid helium temperature. The influence of these impurities in concentrations of a few ppm on the nuclear spin relaxation time was confirmed. I calculated, however, that at these low concentrations most nuclear spins would be too far away from the impurity to undergo rapid relaxation. I resolved this difficulty by introducing the concept of spin diffusion.¹⁷

The theory of Heitler and Teller¹⁸ for nuclear spin relaxation in metals by interaction with conduction electrons predicted reasonably short values for T_1 . I tested this experimentally in a sample of copper powder particles embedded in paraffin and

obtained results¹⁹ in agreement with the Heitler–Teller model. Gorter asked me to measure the T_1 relaxation time of ^7Li in the identical LiCl crystal which he and Broer²⁰ had used in their attempt to detect NMR in 1942. I measured this time to be 10 min at 2.1 K, caused by some undetermined paramagnetic impurity. It is likely that they saturated this resonance on their first scan and consequently no reproducible signal could be found on subsequent traversals. They would have had a better chance if they had used a less pure crystal, or had observed the influence of dispersion on the resonant frequency with a marginal oscillator.

I was interested in showing that fast electron spin exchange, in a way similar to fast electron spin–lattice relaxation, would prevent excessive broadening of a nuclear spin resonance. I therefore grew a crystal of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. The proton resonance was readily observable at room temperature and its width was mostly determined by the local fields of other protons. When the crystal was cooled, the line broadened and assumed a complicated pattern at 20 K. At liquid helium temperatures the resonance was split into 10 well-resolved lines, extending over 400 G, corresponding to a variation of over 7%. These correspond to 10 distinctive proton positions in the unit cell, each with a different time-averaged local field produced by the average magnetization of the copper ions. These paramagnetic shifts²¹ are large, but they attracted much less attention than the Knight shift in metals²² caused by the temperature-independent paramagnetism of conduction electrons.

In May 1948 I defended my Ph.D. thesis ‘Nuclear Magnetic Relaxation’ in a grand public ceremony in the centuries-old aula of Leiden University, where I arrived in white tie and tails in a horse-drawn carriage according to an ancient ritual which has since succumbed to modern efficiency. I had 500 copies of the thesis printed. About half of them were distributed among the Dutch physics faculty and colleagues, family and friends. The remaining copies sold quickly through the offices of the publishing house Nyhoff in The Hague. During the 1950s my thesis was reproduced in various formats in Japan, in The Netherlands, and possibly elsewhere. It was republished in 1961 in the ‘Frontiers in Physics’ series.²³ Some comments and corrections were added in an appendix which relate our earlier work to subsequent developments and improvements. They are of some historical interest.

The article ‘Relaxation Effects in Nuclear Magnetic Resonance Absorption’ which was published¹⁰ in *Physical Review* also received much attention. It is commonly referred to as BPP, an acronym of the names of the authors: Bloembergen, Purcell, and Pound. The paper belongs to the top half dozen physics papers which received most citations in the *Science Citation Index*²⁴ during the period 1945–1988. It attains this distinction as a Citation Classic,²⁵ undoubtedly because a large number of scientists outside of physics have referred to it over an extended period.

In the summer of 1948 I felt that the basic nuclear spin relaxation mechanisms in solids, liquids, and gases were understood. I was invited to speak about this topic at an international conference in Zürich, devoted to postwar advances in high energy and nuclear physics as well. The international renown of Bloch and Purcell was already high, but in 1948 transatlantic travel was still predominantly by ocean liner. Considerations of time and expense prevented them from attending. I was honored to introduce the emerging

field of NMR to a critical audience, which included among others Heitler, Pauli, and Weisskopf. In the hallway I heard afterwards the comment that ‘the experimenters had gotten ahead of the theoreticians’. This reinforced my view that a combination of these two aspects of physics is more than the sum of the separate parts.

I also traveled with Gorter to a low-temperature conference in Oxford, where I became acquainted with B. Bleaney and M. H. L. Pryce who worked on electron spin resonance at microwave frequencies. I also met for the first time with B. V. Rollin and J. Hatton whose work closely paralleled my own.²⁶ I had the impression that they considered NMR as an amateur sport. For me it was not only fun, but also a serious professional pursuit. Therefore our experimental and theoretical results were more systematic and quantitative and received subsequently much wider attention.

I had decided to accept the offer to become a Junior Fellow in the Society of Fellows, a position R. V. Pound had held earlier. I left Leiden and returned to Harvard in January 1949. This switch also marked my taking leave from NMR for several years. For better or for worse, I decided to become familiar with other aspects of physics. For starters, I wanted to acquire some first-hand experience with microwave techniques. I studied the electron spin resonance at the transition from ferromagnetic to paramagnetic resonance near the Curie point of nickel.²⁷ Next, I joined the Harvard cyclotron group to learn some nuclear physics. At the end of my term in the Society of Fellows I obtained a tenured faculty position in the Division of Engineering and Applied Physics at Harvard in July 1951. There was no vacancy in the Physics Department, where R. V. Pound, E. M. Purcell, and N. F. Ramsey already directed experimental research programs in magnetic resonance. Research in solid state physics was to be carried out in the Division, headed at that time by J. H. Van Vleck as Dean. I was glad to return to NMR and apply its techniques to the study of solids. Although the NMR enterprise had grown enormously during the intervening years 1949 to 1951, I found that many nuggets remained to be unearthed. It has remained a fertile field up to the present.

Nicolaas Bloembergen. b 1920. Phil. Cand., 1941, Phil. Drs., 1943, University of Utrecht, Dr. Phil., 1948, University of Leiden, The Netherlands. Research for Ph.D. thesis entitled 'Nuclear Magnetic Relaxation' carried out at Harvard University under the guidance of E. M. Purcell. Postdoctoral work in Leiden, 1947–48. Junior Fellow, 1949–1951; Tenured Professor at Harvard University since 1951. Nobel Prize for Physics, 1981. Currently, Gerhard Gade University Professor, Emeritus. Approx. 350 publications, including two monographs. Research specialties: magnetic relaxation, masers and lasers, nonlinear optics.

Bloom, Myer: Personal Views of NMR History

Myer Bloom

Department of Physics, University of British Columbia, Vancouver, BC, Canada

McGILL UNIVERSITY (1949–50): NUCLEAR PHYSICS

I first heard of NMR in late 1948 while an undergraduate in the final year of the mathematics and physics program at McGill University. A speaker at the weekly colloquium, Karl Darrow, then Secretary of the American Physical Society, told us about the work of the Harvard and Stanford groups and predicted that NMR would ultimately become a major research area in its own right. Furthermore, he informed us that NMR experiments were being carried out at the McGill Radiation (Nuclear Physics) Laboratory. As a consequence, I spent a year doing an M.Sc. thesis in NMR. It may seem odd now that my introduction to NMR was in a nuclear physics laboratory, but the majority of NMR papers published in that era involved measurements of nuclear magnetic moments that are now listed in isotope tables. This subfield was used up in short order and has by now disappeared completely from the NMR culture.

Although I had the (mistaken) impression in 1950 that nuclear physics was going to be the most exciting subfield in physics for the next decade, I had learned as a summer student researcher at Chalk River (Canada's atomic energy laboratory) about the use of neutron diffraction to determine the positions of hydrogen atoms in crystalline solids. Having only one electron, hydrogen atoms are essentially invisible to X-rays in the presence of heavy atoms. The isotopes of hydrogen do scatter neutrons as well as heavy elements, better than most in fact, so that neutron diffraction renders them visible. By now, neutron diffraction has become a standard tool in crystallography but only a few people appreciated its potential value at that time. Having been sensitized by this experience, it is not surprising that my M.Sc. thesis¹ was based on the 1949 paper by the Harvard group² in which accurate estimates of proton–proton distances in solids were obtained from second moments of proton NMR lines. The rigorous interpretation of second moments underlying this type of crystallographic study had been established in Van Vleck's classic theoretical paper.³

UNIVERSITY OF ILLINOIS (1950–54)

I went to Illinois as a student in the Ph.D. program with the intention of studying nuclear physics, but adopted NMR as a research field for my Ph.D. thesis immediately after meeting Charlie Slichter. As a lowly 'Instructor', Charlie did not yet have sufficient seniority to supervise graduate students officially, but a lively group was already gathering about him. Richard Norberg was a worldly-wise, experienced graduate student who plays an important role in my narrative. Dick was by then well advanced in his experimental study of the

hydrogen–palladium system, perhaps the first serious study of a solid state system carried out using NMR. He had actually overlapped with the legendary Erwin Hahn, recently departed for Stanford, and had many amusing stories to tell about the joyous approach to the study of natural phenomena personified by Hahn.

An important feature of the NMR scene in Urbana was the presence of Herb Gutowsky and his group in the Chemistry Department. Gutowsky and Slichter had known each other from their Harvard days, and their graduate students and visitors interacted in a completely natural way. This interaction proved to be important to my ultimate choice of a Ph.D. thesis topic.

FREE MAGNETIC INDUCTION IN PURE NUCLEAR QUADRUPOLE RESONANCE

Dave McCall, then a graduate student in Gutowsky's laboratory, was studying the recently discovered⁴ 'nuclear quadrupole resonance' (NQR) signals of the ³⁵Cl and ³⁷Cl isotopes in solids. In this experiment, no static external magnetic field is used and the nuclear spin energy levels are due to the coupling of the nuclear quadrupole moment with the electric field gradient. McCall was using a horribly nonlinear, but sensitive, device characterized as a 'super-regenerative oscillator–detector'. This instrument had proven to be effective for the detection of NQR of nuclei such as ³⁵Cl and ³⁷Cl having small magnetic moments. Dave explained to me that the theory of the instrument⁵ postulated that, under resonance conditions, a nuclear magnetic induction signal provided the initial condition for the onset of oscillations when the instrument was operated in a 'pulse–quench' mode. The theory had, however, only been established for NMR and Dave assumed that similar conditions obtained for NQR. This stimulated me to consider the theory for the magnetic induction signal for a spin- $\frac{3}{2}$ system in zero magnetic field, having a quadrupolar splitting and subjected to one or more rf pulses applied close to the quadrupolar splitting frequency. My calculations showed that the type of magnetic free induction and spin echo signals found by Erwin Hahn⁶ in NMR should also be observable in NQR. That this should happen was not immediately obvious since the spin system is initially unpolarized in zero magnetic field when the $I_z = \pm m$ states are degenerate and equally populated. In modern terms, however, we would say that the difference in population between the pairs of states characterized by $I_z = \pm \frac{1}{2}$ and $\pm \frac{3}{2}$ causes a tensor polarization to be established at equilibrium. The application of rf pulses breaks the quadrupolar symmetry allowing tensor polarization to be transferred to vector polarization via precession induced by the quadrupolar interactions. The relevance of these symmetry considerations was pointed out to me by Slichter.

The first observation of an NQR spin echo was made shortly thereafter on the ³⁵Cl signal in NaClO₃ by Dick Norberg who had long since completed his Ph.D. thesis and had a broadband pulse spectrometer suitable for searching for such a signal. It turned out that, unbeknownst to us, Erwin Hahn and his student Bernie Herzog were also hot on the trail of NQR spin echoes; they detected the echoes at about the same time as we did as indicated by our concurrent publications.^{7,8} I subsequently

carried out a systematic study of NQR spin echoes and the main results of my thesis⁹ were published jointly with Hahn and Herzog.¹⁰ In closing this section, I wish to express my appreciation to both Charlie Slichter and Dick Norberg, who contributed to the conceptual and practical aspects of detecting magnetic induction in NQR and who unselfishly insisted that they should not participate in the final paper which owed so much to them.

KAMERLINGH ONNES LABORATORIUM, UNIVERSITY OF LEIDEN (1954–56): LOW-TEMPERATURE PHYSICS

In 1954, I went to the Kamerlingh Onnes Laboratory in Leiden on a National Research Council of Canada Travelling Fellowship. The K.O. lab was a dominant force in low-temperature physics from 1908, when Kamerlingh Onnes first liquefied helium, to the mid-1950s. Its director in 1954 was Professor C. J. Gorter, known primarily as a leading figure in low-temperature research and also for his two valiant, though unsuccessful, attempts to detect NMR^{11,12} and for his proposal of the ‘Rabi method’ of doing magnetic resonance in atomic and molecular beam experiments.¹³ Professor Gorter induced Nicolaas Bloembergen, who is of Dutch origin, to present his Ph.D. thesis, based on work carried out at Harvard University, to the University of Leiden¹⁴ and to do some postdoctoral research there. The results of Bloembergen’s Leiden researches¹⁵ are of considerable historical interest since they indicate that the failure of Gorter and Broer¹² to detect NMR can be attributed to the high purity of the alkali halide solids used in their search, resulting in extremely long spin–lattice relaxation times in the liquid helium temperature range that rendered the NMR signals invisible. For psychological reasons, these initial searches for NMR seem to have been carried out from the perspective of low-temperature physics, the mandate of the K.O. lab so to speak. Looking back, it appears to me that Gorter’s failure to be the first to undertake a successful NMR experiment in a bulk sample was due to a combination of bad luck and the limitations of this low-temperature perspective.

Leiden was a wonderful place for a neophyte like myself to learn low-temperature physics. The Kamerlingh Onnes Laboratory had been designed around an instrument makers school and the teachers in this outstanding school were master technicians with the title *Meester* who worked directly with the low-temperature scientists. Visitors were treated with great courtesy by the *Meesters* who helped them immeasurably both in learning Dutch and acquiring the lore of low-temperature experimental methodology. I decided to participate in the ongoing research program by joining the group of Nico Poulis, who was using NMR effectively to study magnetic phase transitions in the liquid helium range. While helping the Poulis group, I would construct a pulsed spectrometer in order to introduce spin echo techniques to the K.O. lab. I wasn’t quite sure what I planned to do with the pulse spectrometer and postponed that decision to a later day.

The day-to-day manner in which physics was done in the K.O. lab was totally different from anything in my previous experience. Almost all experiments involved the use of liquid helium, which was a precious commodity to be handled with

care and in a systematic manner. It was a matter of pride that some of the procedures worked out by Kamerlingh Onnes and the *Meesters* were still being used! Helium was liquefied only on the specific day of each week set aside for measurements; the other days of the week were spent thinking carefully about the meaning of the last set of measurements and preparing for the next. The lab thus had a rhythm into which individual researchers had to fit the style and personality of their work. As a new Ph.D. from the newly-emerging NMR culture, this took some getting used to. I had become accustomed to having my own pulsed NMR rig with which I could do experiments or just fool around with whenever I felt like it.

Another cultural difference was the decoupling in Leiden between theory (in the Lorentz Institute) and experiment (in the K.O. lab). Though these were in adjoining buildings, it seemed that the experimental and theoretical physicists met each other only on the evening of the historical *Ehrenfest Colloquium*. An exception was Professor Gorter who had a well-developed theoretical intuition and interacted strongly with theoreticians (cf. his explanation with Van Vleck¹⁶ of exchange narrowing in NMR). Compare this separation of theory and experiment with the American style of doing physics as characterized by Dyson’s perceptive comments¹⁷ on the famous Bloembergen, Purcell, and Pound paper:¹⁸ ‘It is one of the finest examples of the American style of physics, with experiment and theory working together as inexorably as a steam-roller and squashing a problem flat’. I came to appreciate the educational value of teaching ‘living theory’ to experimentalists, as was done in Illinois, only after starting to work in Leiden.

SPIN–LATTICE RELAXATION BY MAGNONS

My lack of appreciation of the importance and intensity of this difference in working styles led ultimately to some profound difficulties in my working relationships in the K.O. lab. During my first year in Leiden, the Poulis group had initiated a study of the temperature dependence of T_1 in the antiferromagnetic phase of $\text{CuCl}_2 \cdot 6\text{H}_2\text{O}$. They found an extremely strong variation of T_1 with temperature in the liquid helium temperature range, T_1 increasing by about three orders of magnitude (from a few ms to a few seconds) as the temperature was decreased from 4.2 K to 1.2 K.¹⁹ This behavior generated lots of excitement and speculation in the lab but no progress was made over a period of months on its quantitative interpretation. The K.O. lab was closed over the Easter holiday period, but I didn’t go on holiday and instead spent my time thinking hard about the T_1 results. I found that the temperature dependence of the relaxation rate ($1/T_1$) correlated well with the deviations $\Delta M_{\pm} = M_0 - M_{\pm}(T)$ of the sublattice magnetizations from their saturation values, as inferred from the temperature dependence of the proton Larmor frequency measured carefully by the Poulis group over the previous year. Furthermore, I found that if I associated $\Delta M_{\pm}$ with magnetic particles traveling through the magnetic sublattices with a constant velocity derived from the hopping of spins between neighboring Cu atoms due to the exchange interaction, I obtained good quantitative agreement with the measured values of T_1 in the low-temperature regime. Needless to say, I was very excited by the ease with which I could deal with relaxation due to particles associated with spin waves (I believe that the term *magnon* had not yet been

invented for such particles at that time), more so as I only understood what I was doing in an intuitive manner. The first person to appear in the lab towards the end of the holiday was Professor Gorter and I immediately blurted out my 'great discovery'. He immediately recognized that I was proposing a type of spin wave model and urged me to visit a new staff member at the Lorentz, Jan van Kranendonk, who was working on a general theory of spin waves in ferro- and antiferromagnetic materials. This led ultimately to a theory of nuclear spin-lattice relaxation via coupling with magnons, formulated with characteristic elegance by van Kranendonk.²⁰ When the experimentalists returned, my excited presentation of the correlation between $\Delta M_{\pm}$ and $1/T_1$ was met to my dismay not with wild enthusiasm, but only in a polite, subdued manner. Then, when I revealed that I had begun talking to van K. about making a real theory, the roof fell in and I found myself excommunicated in the lab. As I learned later, this behavior was a reaction to previous interactions with theoreticians who had in the eyes of the experimentalists exploited them and their data without adequate acknowledgement.

MOLECULAR HYDROGEN—GAS, LIQUID, AND SOLID

Fortunately, I had nearly finished building my pulse spectrometer by then. The fast recovery 30 MHz (Mc/s in those days) amplifier that had given me some trouble and was being built by the electronics shop at Philips had arrived. I could now put everything together, test the spectrometer and prepare for some experiments at the beginning of my second year in September 1955. I needed an interesting problem, however, especially since I would have to go it alone and could no longer just fit myself into the experimental program of the NMR group in the K.O. lab. An idea for an experiment well suited to my pulse spectrometer emerged from a talk at the September 1955 Low Temperature Conference in Paris by B. V. Rollin²¹ of Oxford University. Rollin reported motional narrowing experiments on solid H_2 and D_2 near their melting points which provided a measure of the temperature dependence of the molecular diffusion constants. It was clear that pulse techniques could give more reliable T_2 measurements over a wider temperature range than the linewidth measurements of Rollin and Watson.²¹ An attractive aspect of the H_2 study to me was that liquid hydrogen was available in the K.O. lab any day (or night) of the week so that I could follow my own whims on when and how to work.

The study of self-diffusion in solid H_2 and HD did, in fact, ultimately lead to interesting physics.^{22c} Of more long-term interest to me, however, was the unexpected observation of a strong NMR signal from the gas before we had condensed it into our sample holder. The nuclear magnetization of H_2 gas at 20 K is only about a factor of five smaller than H_2O at room temperature, so I should not have been surprised! The observation of this signal allowed me to study T_1 in the gas^{22a} as well as the liquid^{22b} and solid^{22c} phases. In all of these measurements, T_1 was directly related to the rate of molecular reorientation and could be used to investigate the properties of the relatively weak anisotropic intermolecular interactions. Though this mechanism had been identified in the original BPP paper,^{14,18} it had not been followed up to extract useful

molecular information. After I returned to Canada, the study of T_1 in molecular gases led to a large program in our laboratory at the University of British Columbia over a period of more than 10 years.²³ This program allowed us to explore the nature of intermolecular interactions in a special way using NMR.

The significance of the experimental data was enhanced considerably by the development of a fundamental theory of spin-lattice relaxation which was due mostly to Irwin Oppenheim.^{24,25} Oppenheim was a postdoctoral fellow (PDF) at the Lorentz Institute during my second year in Leiden and the idea of relating T_1 in molecular gases in a basic way to intermolecular interactions arose naturally from the many discussions we had after becoming friends in Leiden. The actual development of a theory took place after we had both returned to North America and was influenced by experimental studies of T_1 in molecular gases that I discuss later.

UNIVERSITY OF BRITISH COLUMBIA (1956–PRESENT DAY): MORE NQR—A GENERAL TWO-LEVEL SYSTEM

After my two years as a PDF in Leiden, I joined George Volkoff as a research associate at the University of British Columbia, where I have been ever since. I wanted to return to Canada and was aware of the work of Volkoff and his students on the measurement and analysis of NMR spectra under the combined effects of Zeeman and quadrupolar interactions for spins with $I \geq 1$ in single crystals. When I arrived, George and his Ph.D. student Lloyd Robinson were puzzled by the dependence of the intensity of ^{27}Al NMR lines in a spodumene single crystal on the magnitude and orientation of the external magnetic field. At certain crystal orientations and intermediate fields (i.e. when the Zeeman and quadrupolar interactions were of comparable magnitude), the intensities of certain transitions went through zero when the transition probability was predicted to be a maximum.²⁶ Crucial to the understanding of this apparently paradoxical result was the fact that Robinson was using a crossed coil spectrometer in these experiments. We finally realized that for any two-level, or pseudo two-level system such as a single pair of levels being resonated in the ^{27}Al ($I = \frac{5}{2}$) system, only three variables are required to characterize all measurements made on the system and one can derive a set of equations analogous to the Bloch equations to describe its most general dynamical behavior.²⁷ This feature of any two-level system is now known and understood by any beginning student in NMR who has learned the elements of the density matrix description of spin systems. However, density matrix theory had only just been developed by Al Redfield in 1957²⁸ and the words *density matrix* appear neither in our paper nor in the more general formulation of this property of two-level systems carried out independently at about the same time by Hellwarth et al.²⁹ We derived a set of Bloch equations for a general two-level system and were able to account for Robinson's experimental results²⁶ by showing²⁷ that, while the transition probability is proportional to $|\langle I_x \rangle|^2$, the detected signal is proportional to the product of $\langle I_x \rangle$ and $\langle I_y \rangle$ for transmitter and detector coils oriented along the x and y axes, respectively, in a crossed coil system. In general, the precession is elliptically polarized; zero signal occurs for linear

polarization when one of the coils is oriented perpendicular to the direction of polarization.

SPIN-LATTICE RELAXATION IN H₂ GAS

When I arrived at U.B.C., George Volkoff encouraged me to take some new initiatives and generously made his NRC operating grant available to me for whatever I chose to do. Since I had a lot of unfinished business to complete with pulsed spin echo techniques, I once more built a spin echo spectrometer to operate with a 7000 G permanent magnet that was available in the lab. I was joined soon by a Ph.D. student, Max Lipsicas, who had written to me after reading my Leiden papers on T_1 in H₂ gas, liquid, and solid²² to propose a study of T_1 in H₂ gas as a function of the ratio of *ortho*- to *para*-H₂ over a wide temperature range. Max hoped that such measurements would provide a novel method of determining the anisotropic interactions between H₂ molecules responsible for collision-induced changes in molecular orientation in the gas phase. In fact, Max Lipsicas's measurements³⁰ turned out to be very interesting and stimulated a theory of T_1 in molecular gases in which the general theory of spin-lattice relaxation was integrated with a treatment of molecular collisions from first principles.^{23,24} One of the surprising features of the initial measurements, which was explained in terms of the radial dependence of the various terms in the anisotropic intermolecular potential, was the qualitative difference in the temperature dependence of the average cross-section for molecular reorientation of *ortho*-H₂ molecules as a result of *ortho-ortho* and *ortho-para* collisions. This led to an accidental cancellation of the variation with temperature of the average cross-section between 100 K and 300 K for normal H₂, i.e. 75% *ortho*-H₂.³⁰

Space does not allow me to go into detail on the subsequent studies of molecular reorientation in various gases of different molecular symmetry^{23–25,31} as well as their extension to molecular liquids and solids.³² These studies extended over a period of more than 15 years and were carried out by a large number of talented students and PDFs, some of whom have become well known for their work in NMR and other fields (e.g. Walter Hardy, Ron Dong, Peter Beckmann, and Elliott Burnell).

THE TRANSVERSE STERN-GERLACH EXPERIMENT

In the early 1960s, I was diverted into thinking about a different aspect of magnetic resonance as a result of a series of coffee-room discussions with a nuclear physicist colleague, Karl Erdman. He speculated on whether one could improve the accuracy of measurements of the g -factor of the free electron by somehow detecting resonant transitions at the frequency $\omega_L - \omega_c$ corresponding to the difference between the Larmor and cyclotron frequencies and thereby measuring $g - 2$. Upon looking into the selection rules for this type of transition, which involves a simultaneous change of spin and cyclotron quantum numbers, I found that the interaction required to produce the transitions was of the Stern–Gerlach type in the sense that it involved a magnetic field *gradient*! This led to a theoretical formulation of a generalization

of the Stern–Gerlach experiment, which we called the *transverse Stern–Gerlach (TS–G) experiment*.³³ The theory demonstrated that, for neutral atoms, the application of a rotating *inhomogeneous* magnetic field near ω_L gives rise to ‘space quantization’, with the angular momentum being quantized along $\mathbf{H}_{\text{eff}}$, the ‘effective field in the rotating reference frame’. (The term ‘space quantization’ here means that the Stern–Gerlach apparatus sets up a correlation between the momentum of the particles in the beam and the component of angular momentum of the particles along the direction of quantization.) The TS–G experiment thus demonstrates that $\mathbf{H}_{\text{eff}}$ is not only of pedagogical importance but also has an important operational significance in the quantum mechanical description of NMR.

The main motivation for exploring the TS–G experiment was that we perceived a possible advantage in doing magnetic resonance on beams of charged particles. We have never succeeded in doing such an experiment. In 1964–65, however, after a sabbatical leave at Harvard University spent partly with Norman Ramsey's group, I came to the conclusion that it would be interesting to illustrate the conceptual aspects of the TS–G experiment by doing an experiment on neutral atoms. Eric Enga, a gifted experimentalist, carried out this experiment in collaboration with Hin Lew at the National Research Council laboratories in Ottawa³⁴ and verified the predictions of the theory.³³

The TS–G experiment can be regarded, in retrospect, as a special case of magnetic resonance using an interaction with a spatial gradient—in essence, the gradient gives rise to a force leading to momentum changes. In standard magnetic resonance experiments, the resonance is detected by magnetic induction rather than by force effects. Yet, aside from an experiment analogous to the TS–G experiment using oscillating, inhomogeneous electric fields,^{34a} the additional freedom afforded by the possibility of using force detection remained unexplored from 1967 until just recently when several exciting developments have taken place. An optical S–G experiment, using the spatial gradient of a resonant, laser-produced electromagnetic field, has been successfully carried out on particle beams,³⁵ a trap of neutral atoms based on the TS–G force has been proposed and developed,³⁶ and the theory of magnetic resonance TS–G experiments on beams³⁷ and trapped ions has been explored.³⁸ Most exciting of all, however, and of great potential importance to workers in NMR is the proposal by Sidles³⁹ to detect NMR in solids using the techniques of atomic force microscopy (AFM). According to Sidles's calculations, there is no theoretical reason why it will not be possible, ultimately, to detect the NMR signal via AFM methods for a *single spin* in a solid! The basic principle of magnetic resonance detection via AFM has recently been verified by Nino Yannoni and Daniel Rugar at the IBM Almaden laboratory in an ESR–AFM experiment on a 30 ng sample of diphenylpicrylhydrazil;⁴⁰ the same group has recently detected an NMR signal from a sample of NH₄NO₃ with a sensitivity of about 2×10^{13} protons.^a At the time of writing (November 1993), this field is moving rapidly and it is not clear what the ultimate sensitivity of this method of NMR detection will be.

MEMBRANES

One pattern in my life that I have maintained with religious fervor has been to take a sabbatical leave from U.B.C. every seventh year. These breaks with normal routine have invariably generated unpredictable changes in my research activities which made life more interesting in the long term. The 1971–72 leave in France, partly with the Orsay Liquid Crystal Group, proved to be especially important to me. Pierre-Gilles de Gennes had generated an exciting atmosphere in Orsay in which people from different scientific backgrounds communicated with each other on problems related to liquid crystals. The ferment created by this environment led ultimately to the award of the 1991 Nobel Prize in Physics to De Gennes.

When I arrived in Orsay in the late summer of 1971, I was asked by the head of the NMR group (Claude Froidevaux) to share an office with Jean Charvolin, who was then a young researcher in the process of preparing his Ph.D. thesis. Charvolin had just completed a set of proton magnetic resonance (^1H NMR) experiments on soap–water solutions in collaboration with Paul Rigny of Saclay⁴¹ and Claude hoped that I would act as a critic of the NMR data at the interpretative stage. The system being studied, potassium palmitate, forms liquid crystals whose symmetry depends on the concentration of potassium palmitate molecules in water. It had recently been discovered that biological membranes were fluid under physiological conditions and that the lamellar symmetry of the smectic A phase of the soap–water system was identical to that of membranes. For this reason, the soap–water system could be considered as a simple model for some structural features of model membranes.

The ^1H NMR properties of these systems are unusual. The ‘powder lineshape’ had been described as a *superlorentzian* because the lines are sharp but decrease more slowly in the wings than does a Lorentzian. In their definitive study, Charvolin and Rigny⁴² showed that unlike NMR lines associated with isotropic fluids, the motionally averaged dipolar interaction $\langle H_{\text{dip}} \rangle$ is not zero in a membrane-like system. From an NMR perspective this is the crucial feature of *anisotropic fluids* that distinguishes them from the more familiar isotropic fluids. In fact the main features of *superlorentzian* lines can be easily explained^{43,44} in terms of a superposition of dipolar broadened lines having the property that $\langle H_{\text{dip}} \rangle \propto (3\cos^2\theta - 1)$, where θ is the angle between the external magnetic field and the normal to the bilayer surface, the liquid crystal director.

Having learned about the physical properties of fluid membranes from a familiar NMR perspective, I was sensitized to the excitement in biological circles aroused by the growing realization that cell membranes were *universally* in a lamellar fluid (‘liquid crystalline’) phase under physiological conditions as proposed by Singer and Nicolson.⁴⁵ When I returned to Vancouver, I wondered whether to embark on some serious experimental studies of membranes. A perverse encouragement to move in this direction was an apparent lack of ease with nonzero average tensor interactions such as dipolar interactions that seemed to be present in some of the NMR studies of membranes that began to appear in the literature.

Eventually, with the help of an equipment grant from NRC and a special grant to develop interdisciplinary research from

a Canadian foundation (Killam), we formed a group to work on membrane-related problems. I have often been asked by physicists how I managed to make the transition into such an enormous area of science as membrane research ‘on my own’. Looking back, however, I am impressed by the size and range of expertise of our initial group and those that evolved from it during the following few years. The transition involved a lively and interesting group effort and was certainly not made ‘on my own’. The initial group included my colleagues Elliott Burnell in chemistry and Gerald Weeks in microbiology; research associates Christine Nicol in microbiology, Tim Higgs in chemistry, and Marko Valic in physics; PDFs Jim Davis and Alex MacKay; visiting professors Steve Roeder and Ken Jeffrey, followed later by Bruno Maraviglia, Ole Mouritsen, Paul Callaghan, Jerzy Blicharski, and Philippe Devaux. A number of important collaborative studies also developed with short term visitors as I mention below.

Our first effort involved the solution of a subtle and controversial motional averaging problem in the ^1H NMR of vesicular bilayer structures⁴⁶ in relation to the special nature of the origin of the superlorentzian shapes of dipolar broadened lines in powder dispersions of membranes.⁴³ The subtlety of this problem arises because of the scaling of $\langle H_{\text{dip}} \rangle$ for all the protons in an individual lipid molecule with $(3\cos^2\theta - 1)$ as mentioned above. Under these conditions, the ^1H NMR lineshape resulting from modulation of θ due to isotropic vesicle tumbling is not given by the standard theory of motional averaging, i.e. a Lorentzian line does not obtain. Rather, each isochromat in the quasi-continuous ^1H NMR spectrum of an oriented bilayer is *separately* motionally averaged leading to a complex superposition of Lorentzian lines. The extraction of useful information about membranes from ^1H NMR requires great care.

A major advance in the study of membranes using NMR was the introduction of the quadrupolar echo method of doing ^2H NMR spectroscopy.⁴⁶ This was done by Jim Davis immediately after his arrival in our lab. We had been discussing how a decay of the *solid echo*, i.e. the echo following a $90_x - \tau - 90_y$ pulse sequence in the ^1H NMR signal of a dipolar-broadened membrane sample, required the influence of dipolar couplings between protons on different methylenes with its accompanying spin diffusion along the lipid chains, since the solid echo pulse sequence would refocus all the phase accumulated by the protons of isolated two-spin systems. Jim immediately appreciated that a consequence of this was that the influence of quadrupolar interactions of a nucleus having $I = 1$ could be *completely* refocused by the same pulse sequence. The use of the quadrupolar echo, though conceptually simple, was extremely important in that it opened up the possibility of producing distortion-free ^2H NMR spectra. For deuterons in lipid systems, the timescale for dipolar interactions is at least an order of magnitude greater than that of the quadrupolar interactions. As a result, the ^2H NMR spectrum can be represented, to a good approximation, as a superposition of *Pake doublets*.⁴⁷ Analysis of the spectrum of Pake doublet splittings, e.g. using the method of ‘dePakeing’,⁴⁸ provides a quantitative picture of membrane fluidity. This has proven to be crucial in obtaining useful information about such important questions as the nature of the interaction between lipids and biologically important molecules such as proteins, peptides, or cholesterol in membranes. As a consequence, ^2H NMR is now

recognized as a major technique in the determination of the physical properties of biological and model membranes.⁴⁹

Space does not allow a detailed description of the role of ²H NMR in membrane research. I should, however, mention the enrichment of our own work that resulted from collaborations with a number of outstanding biophysicists and biochemists from other institutions: Ian Smith of the National Research Council of Canada, Bob Cushley of Simon Fraser University, Rick Dahlquist of the University of Oregon, Philippe Devaux of the Institut de Biologie-Physico-Chimique in Paris, and Thomas Bayerl of the Technical University of Munich. Jim Davis's realization of how to use the quadrupolar echo as a means of doing distortion-free ²H NMR attracted these people to our laboratory with proposals of specific experiments and with the capability of preparing and characterizing materials of interest in the study of membranes, a capability that we did not have. Some of our visitors came to us simply to learn broadline NMR. They soon had their own spectrometers and became independent, but they left us with much lore on membrane biophysics and biochemistry that is difficult to acquire by reading published papers.

We also attracted researchers from other departments of our own university: Pieter Cullis (biochemistry), David Godin (pharmacology), Neil Kitson (dermatology), Ian Taylor (botany), as well as PDFs and students with diverse backgrounds: Klaas-Pieter Datema, a physicist from the Netherlands; Michel Lafleur, a physical chemist from Quebec; Myrna Monck, a biochemist from U.B.C.; François Macquaire, a biophysicist from France; Peter Pauls, a botanist from Ontario; Michel Roux, a biochemist from France; Olle Söderman, a physical chemist from Sweden; Jenifer Thewalt, a biophysicist from Vancouver; Clare Morrison, Frank Nezil, and Ed Sternin, all U.B.C. Ph.D. students.

For me, the thrill of working on biologically oriented problems has been connected with the realization that Nature in 'designing its materials' via evolutionary processes has invariably optimized the physical properties of the materials for the survival of the organism. Appreciation of this optimization arose from NMR studies showing that cholesterol or equivalent sterol molecules are ubiquitous in the fluid, plasma (outer) membranes of eukaryotic cells and have had a definitive influence on their special physical properties.^{50,51} The unusual, ultrasoft nature of most biological materials is related to membrane fluidity and makes NMR especially useful in their study. I have tried to explain elsewhere⁵² the special interest of these soft materials in relation to projected future developments in the physics of condensed matter.

Finally, I mention the connections with modern medicine inevitably stimulated by the study of biological systems using NMR. Though only peripherally involved, I have found this area of research particularly rewarding. I am grateful to my friend Ian Smith for having introduced me to Dr. Carolyn Mountford, an Australian biophysicist who had developed a proton NMR method for diagnosing unusual aspects of cancer. As a result of spending part of my 1985–86 sabbatical year with Carolyn's group, I found an interesting application for some of our earlier proton NMR lineshape studies^{43,45} in this medical area.⁵² As important, perhaps, from a psychological perspective were the four months spent in the company of a tenacious, feminist, and competent group working on an important problem involving a complicated spin system. Since returning from Australia, I have noticed that my research group

has also become feminist and tenacious, but this may be a coincidence.

Myer Bloom. b 1928. B.Sc., 1949, M.Sc., 1950, McGill University, Canada, Ph.D., 1954, Physics, University of Illinois, USA (with Charles Slichter). National Research Council of Canada Postdoctorate Travelling Fellow, 1954–56 at the University of Leiden, Holland (with C. J. Gorter). Research associate, 1956–57 (with George Volkoff) and Faculty in Physics, University of British Columbia, 1957–present. Approx. 150 publications. Research specialties: nuclear quadrupole resonance, nuclear spin relaxation and molecular motions in gases, liquids, and solids, the transverse Stern–Gerlach experiment, structure and dynamics of model and biological membranes.

Bodenhausen, Geoffrey: Traveling through the World of Magnetic Resonance in the 1970s

Geoffrey Bodenhausen

Université de Lausanne, Lausanne, Switzerland

As an undergraduate at ETH in Zürich between 1970 and 1974, I had plenty of opportunities to hear about magnetic resonance. Initially, I was not so much attracted by the physicochemical aspects of NMR, but rather by its applications to analytical chemistry. I was greatly impressed by Wilhelm Simon's charisma, and by his fascinating weekly sessions where analytical puzzles ('Probleme der Woche') were eagerly debated in a large auditorium. A set of IR, UV, MS, and NMR spectra were distributed at the outset, and anyone, from undergraduates to senior researchers, could try his or her talent and suggest molecular structures that appeared to be compatible with the spectral evidence. NMR was clearly the richest and most intriguing source of information. In my third undergraduate year, I had my first hands-on encounter with an NMR spectrometer in the analytical teaching laboratory, but this turned out to be disappointing. We tried to carry out some tickling experiments—in vain, because the stability of the machine was not sufficient for such delicate double-resonance methods. To make matters worse, we were constantly interrupted by graduate students who kept rushing into the lab with samples that they had just cooked up, which they insisted should be put immediately into the NMR spectrometer. Needless to say, we did not approve of the way these mundane measurements were taking precedence over our intellectual endeavor. This episode may have contributed to my attitude to synthetic chemists, and also turned my attention away from NMR, for I was equally fascinated by fluorescence, electrochemistry, ion-selective electrodes, in fact anything that would allow one to probe the mysteries of matter. To be truthful, Richard Ernst's lectures on Fourier transforms and data processing appeared a bit dry. Yet I could not resist the appeal of magnetism, and asked to join his group during my last undergraduate term ('Diplomarbeit'). Richard suggested that I should look into Overhauser effects. He provided a list of ideas dated January 20th 1974, which I'll attempt to translate literally: 'The problem: One should consider the possibility of systematically determining the relaxation parameters of a coupled spin system through a complete set of Overhauser experiments. Detailed problems. Formal analysis of the coupled set of equations for special and general cases. Formal structure. Number of independent equations. Possibilities for determining the parameters. Determination of measurement errors. Calculation of relaxation parameters for a chosen molecule. Proposals for organizing the measurements. Experimental tests and interpretation of the results.' For the benefit of today's reader, I should explain that the 'complete set of Overhauser experiments' referred to all (!) possible single-, double- and multiple-irradiation experiments. The

'coupled set of equations' refers to the master equation with a $2^N \times 2^N$ -dimensional matrix containing the transition probabilities between the 2^N eigenstates of a system of N spins with $I = \frac{1}{2}$. Needless to say, I did not quite manage to run through all of these ideas in the eight weeks of a summer term. In fact, I'm still working on this job nearly 20 years later: our recent efforts to quench spin diffusion¹ may be regarded a partial attempt to fulfill Richard's expectations as he wrote them out back in 1974.

Why did I embark on a seemingly endless Odyssey through the NMR community rather than stay at ETH for a Ph.D.? To be sure, I largely failed to appreciate the depth of Richard's research. In retrospect, I realize that Fourier imaging was developed there right before my eyes, on the blackboard, when Richard came back from a meeting in the US. He must have heard Paul Lauterbur speak of 'Zeugmatography', the early version of NMR imaging, which originally relied on the back-projection method. Richard asked around his group for volunteers who would be willing to develop Fourier imaging, and Anil Kumar and Dieter Welti came forward.² This must have been one of the key moments of NMR history, but, to be honest, I did not perceive anything particularly exciting. I was much more preoccupied with the duration of a typical Ph.D. thesis in Zürich. In fact, when I returned there in 1980, after three years in Oxford, a year in San Diego, and nearly two years in Massachusetts, I met a former classmate who had remained in Zürich for all those years, and who was about to begin writing up his thesis. At that point, I felt immensely grateful that I'd seen some of the world, and I still believe that mobility is worthwhile.

Why did I choose to move to Oxford? The initial idea came after an eloquent lecture that Rex Richards gave in Zürich in 1974. He talked about resolving protein structure with the help of paramagnetic ions, which allowed him 'to peel the molecule like an onion'. He also mentioned phosphorus NMR as an intracellular pH meter. The very next day I wrote to Professor Richards to ask him whether I could join his Oxford group. He promptly replied that he had no space available, but that a young man was just starting up a new group across the road in physical chemistry. This young man was Ray Freeman. He may have been young from Rex's perspective (Ray had been one of his D.Phil. students), but when I first met him in the summer of 1974, I was mightily impressed. Ray must have been 42 in 1974, which happens to be my age at the time of writing these lines. I initially called him 'Sir', not knowing that 'Dr. Freeman' would have been more appropriate, and completely failing to perceive that he would have preferred to be called 'Ray'. In spite of my insecurity about manners and language, I was delighted about Oxford. However, once in the lab, in January 1975, I was perturbed by the lack of structure and the absence of guidelines. Gone were Richard Ernst's long lists of instructions. There was, in fact, an 'idea book' in the lab where anyone could enter his fantasies, but ideas were rarely handed down from the top. It took me years to adjust. In this period, I greatly benefitted from the stimulation provided by people such as Gareth Morris and David Turner. Though I was tempted to look down on them for what I perceived as a lack of formal training (they'd never heard of convolution integrals!), I marveled in secrecy at their independence. I slowly came to realize that intellectual autonomy is harder to acquire than a knowledge of calculus. I also began to perceive that research can actually be *fun*, and need not be a calvinistic exercise

in self-discipline. Ray appeared to spend more time looking for cartoons than writing papers. (How can one be so light-hearted!) I could never quite fathom the source of his playful creativity. Some outsiders seem to believe that Ray does not understand quantum mechanical systems. I would rather say that Ray has such a deep, intuitive grasp of energy levels, transitions, coherences, and all the rest, that he simply *doesn't need* to dress them up in mathematical terms. Ray has no use for unitary transformations to work out his coherence transfer pathways, no more than a pro tennis player needs a pocket calculator to master the trajectories of his passing shots.

The last year of my stay in Ray's laboratory was the beginning of the great epoch of acronyms. We were very proud of our first phase cycling recipe,³ which allowed us to remove artifacts that Ray had affectionately dubbed 'phantoms' and 'ghosts'. At that time, the movie theaters featured a film called 'The Exorcist', so that we naturally came to christen our invention 'Exorcycle'. I hoped Ray might dress up as a priest (after all, he had to wear a college gown on occasions), and ride a bicycle while sprinkling holy water. He never agreed to enact this fantasy.

Phase cycling provided a guiding thread for my intellectual endeavor for many years. In retrospect, it seems a very thin thread, but there it was. To exploit this idea, I had to modify various spectrometers to shift radiofrequency phases. I built a digital phase shifter for Ray's CFT-20 in Oxford, and an improved version for Bob and Gitte Vold's homebuilt machine in San Diego. When I moved to the Francis Bitter National Magnet Laboratory at MIT in 1979, Dave Ruben built another phase shifter, with mysterious analog components such as splitters and combiners that I never quite trusted. After my return to ETH, Markus Hintermann built a fast digital device, supposedly under my direction, though I could never quite fathom how it actually worked. But it did, and allowed us to select 'coherence transfer pathways' more or less at will. In the meantime, that expression had become the 'buzz word' of the trade, and given some respectability to the rather mundane world of phase cycling.⁴ As always, once a subject becomes transparent it ceases to be an object of active research. Until someone invents another buzz word. I've recently heard that one should 'project the density operator onto the receiver phase'. Perhaps that sounds good enough to bring new life to phase cycling?

From time to time, research can be a source of frustration. One episode from which I learned a great deal was the invention of INADEQUATE,⁵ which Ray presented at the Experimental NMR Conference (ENC) in Tallahassee, Florida, in 1979. We had invented *exactly* the same sequence, but our applications to proton spectra of nucleotides⁶ must have appeared quite mundane compared to Ray's spectacular unraveling of carbon-carbon couplings in samples with natural isotopic abundance. I gave a muddled, overcrowded talk at ENC, no match for Ray's sharp sense of presenting a 'single selling proposition'. Worst of all, while Ray gleefully talked about his Incredible Natural Abundance Double Quantum Transfer Experiment, I simply didn't have any acronym at all! I really should have dropped out of the field of NMR right there in Tallahassee. . . .

In a sense, my involvement with magnetic resonance is marked by a series of failed opportunities. In 1974, when I joined Richard Ernst's group as undergraduate I opted for the Overhauser project outlined above. In doing so I

actually turned down another suggestion which might have been far more exciting: Richard offered me an opportunity to get involved in the very early stages of two-dimensional correlation spectroscopy. But this didn't happen and I got bogged down in Overhauser effects for much of my career. I missed another opportunity when I left Ray's lab at the end of 1977. We had been playing with variants of heteronuclear correlation spectroscopy, largely inspired by the work of Maudsley and Ernst.⁷ To be truthful, we found it hard to break new ground. But within weeks of my departure from Oxford, Gareth Morris and Ray Freeman came up with their famous INEPT method (Insensitive Nuclei Enhanced by Polarization Transfer).⁸ Today there is hardly any flashy three- or four-dimensional NMR sequence which doesn't incorporate a few INEPT building blocks. Once I had arrived at UCSD in 1978 I again missed an opportunity: I should have listened carefully to Bob and Gitte Vold's teaching on relaxation theory. But I was too much absorbed by the technicalities of coherence transfer to get the overall picture. In recent years, we have made many efforts in Lausanne to develop new approaches to the measurement of relaxation phenomena. Basically, I feel that after all those years I am still driven by a desire to catch up with my failure to penetrate the secrets of relaxation during my stay at UCSD. After moving to MIT in 1979, the same scenario repeated itself: my involvement with solid state NMR was so superficial that I really did not develop much appreciation of the theory. It was long after I left MIT that I came to realize how convenient it would have been to listen more carefully to Bob Griffin's advice. Again, the efforts that we have undertaken in Lausanne in the field of solid state NMR may be regarded as an attempt to catch up with the lost paradise. Perhaps Richard Ernst was most successful in stopping my natural tendency to disperse my attention. When I joined his lab in 1980 as a postdoc, I tried to convince him to start what I thought to be an exciting project (I believe it had to do with phase cycling, for a change). Richard listened carefully, understood the implications and limitations, and commented that my idea would make a nice footnote. . . .

The world of magnetic resonance is wonderfully rich, not simply because of the extraordinary wealth of intriguing ideas, but primarily because of the presence of so many talented people. It is most rewarding to see that this community is constantly being rejuvenated by the arrival of bright and demanding newcomers. Let us hope that their Odysseys will be as rewarding and stimulating as ever.

Bothner-By, Aksel A.: Computer Analysis of High-Resolution NMR Spectra

Aksel A. Bothner-By

Carnegie Mellon University, Pittsburgh, PA, USA

In 1959, Cecile Naar-Colin and I embarked on a study of the high-resolution proton resonance spectra of simple organic molecules with a view to finding out something about their structures, especially their rotameric populations. The top spectrometer frequency then available was 60 MHz and almost all the spectra we recorded were strongly non first order, since the chemical shifts between coupled nuclei were usually just a few times larger than the spin-spin coupling constants. This meant that one could not simply read off the shifts and coupling constants from the observed spectra, and there was an urgent need to be able to compute their values somehow from the observed line positions.

The basic method of calculating what the line positions and intensities should be, given a set of shifts and coupling constants, had been set forth by Hahn and Maxwell,¹ Gutowsky, McCall, and Slichter,² and McConnell, McLean, and Reilly³ in the early 1950s; our guide on how to do this was the beautiful exposition by Pople in the classic book High-Resolution Nuclear Magnetic Resonance.⁴

The successive steps in the calculation can be represented by equations (1)–(5):

$$\mathbf{H} = \sum_{i=1}^{i=n} \nu_i I_{zi} + \sum_{i=1}^{i=n-1} \sum_{j=i+1}^n J_{ij} \mathbf{I}_i \cdot \mathbf{I}_j \quad (1)$$

$$\Lambda = e^{-1} \mathbf{H} e \quad (2)$$

$$\mathbf{A} = e^{-1} \left(\sum_{i=1}^{i=n} I_{+i} \right) e \quad (3)$$

$$\nu_{kl} = \lambda_{kk} - \lambda_{ll} \quad (4)$$

$$s_{kl} = A_{kl}^2 \quad (5)$$

In the first step a square Hamiltonian matrix is constructed which gives the energies and interaction energies of a set of basis states of the nuclei as though each were independently quantized. For protons and other spin- $\frac{1}{2}$ nuclei, the states are symbolized α and β , which designate states (or spin coordinates, or spin functions, or spin wavefunctions) in which

the nuclear spin axis is specified to be parallel or antiparallel to the magnetic field. For two spins, the four possible states would be symbolized $\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, and $\beta\beta$. For the two-spin case, the upper left-hand element in the 4×4 matrix, at the intersection of the row and column each associated with the state $\alpha\alpha$, would have the value $H_{\alpha\alpha,\alpha\alpha} = \nu_A(\frac{1}{2}) + \nu_B(\frac{1}{2}) + J_{AB}(\frac{1}{2})(\frac{1}{2})$. The only basis states which interact are $\alpha\beta$ and $\beta\alpha$, and for these, $H_{\alpha\beta,\beta\alpha} = H_{\beta\alpha,\alpha\beta} = J_{AB}/2$.

In the second step, the matrix $\mathbf{H}$ is diagonalized to get Λ . The process may be thought of as a rotation to a new set of coordinates, and the form of equation (2) is that of a similarity transformation, i.e. expression of the same entity in a new coordinate framework. The term Λ is thus also a Hamiltonian, but expressed in terms of the spin states which do not interact. Only the elements λ_{11} , λ_{22} , λ_{33} , and λ_{44} are nonzero. The eigenvector matrix e specifies the coordinate transformation required.

Thirdly, the transition amplitude matrix, $\mathbf{A}$, between the eigenstates is found by applying the same coordinate transformation to the amplitude matrix calculated for the basis states. This amplitude is unity if exactly one spin flips from α to β in going from one basis state to another, and is zero otherwise.

Finally the transition frequencies, ν_{kl} , and transition intensities, s_{kl} , are obtained by subtracting λ_{ll} from λ_{kk} , and by squaring A_{kl} .

The only nontrivial part of this calculation is the diagonalization. For simple spin systems, such as the AB case, where no basis state interacts with more than one other basis state, the determination of the eigenstates and eigenvectors requires only the solution of a quadratic equation of the form $(H_{kk} - \lambda)(H_{ll} - \lambda) - H_{kl}^2 = 0$. The roots are λ_{kk} and λ_{ll} . Using this fact, Pople was able to provide general algebraic solutions giving the frequencies and intensities of the expected lines for many simple systems such as A_2 , AB, ABX, A_2X_2 . If the system contains groups of spin- $\frac{1}{2}$ nuclei which are magnetically equivalent (i.e. which all have the same chemical shift and which are all equally spin-coupled to each other nucleus in the system), it turns out that the coupling between the spins in the magnetically equivalent group does not affect the appearance of the spectrum, so that it can be arbitrarily taken as zero. This expands the kinds of systems for which closed algebraic solutions can be found to AB_n , A_mB_n , $A_mB_nX_p$, etc. E. Bright Wilson published an elegant exposition⁵ of how group theory could be applied to take advantage of the symmetries in spin systems such as that of 1,3,5-trifluorobenzene, and to reduce the interactions to pairwise ones. These solutions provided a ready means to analyze the spectra of many simple systems, and to extract the shifts and coupling constants from the observed spectra.

Even with the algebraic solutions in hand, the task of tabulating all the line frequencies and intensities and finding the values of shifts and coupling constants giving a spectrum agreeing with the observed one was tedious, error-prone, and time-consuming. The availability of an IBM 650 through the newly-formed Department of Computer Science at the Carnegie Institute of Technology appeared to offer a fast and convenient way to tabulate these spectra, and we set out to write a few programs for specific cases, such as the $X_3AA'X_3'$, applicable to the case of the 2,3-dihalobutanes, which we were then studying. From Alan Perlis, the Director, we received a set of instructions on how to prepare a program for the computer in a language called IT. After a couple of weeks of puzzling, we

produced what we thought would be a working program and brought it to be run. Unfortunately, IT had become obsolete in the interim, and a new language, AT, was now in use. Our second attempt also took about two weeks to write, and, predictably, was also out of date when we got it there. Back, to rewrite in GAT. This time we were barely in time, and, amazingly, to us, it worked. The computer gave us a list in about 2 minutes that it would have taken us 2 days to crank out on a Monroe. We were able to use it for the intended analyses.⁶

Most of the systems we wanted to look at, however, did not fit into the categories for which closed algebraic solutions were available. For systems with three or more interacting states, the algebraic solutions were of formidable complexity, and did not then appear to be practically useful. On the other hand, if the actual values of the shifts and coupling constants are introduced into $\mathbf{H}$, the diagonalization problem becomes a purely numerical one. Numerical methods for the iterative diagonalization of large symmetric real matrices have long been known. One such, the Jacobi method, simply treats the interaction elements in succession, nulling each one by a coordinate transformation as though it were the only one. After each coordinate rotation, the other interaction energies are mixed, but eventually they are all reduced to less than any arbitrarily set limiting value.

It was a straightforward task to write a program which would read in a set of values for shifts and coupling constants, evaluate the numerical Hamiltonian according to equation (1), perform the diagonalization by the Jacobi method, and produce a list of frequencies and intensities for the expected spectrum. With the help of Carl Saalbach, our first program, FREQINT, was completed. It worked without problems, but it did not meet the central need. The difficulty was that it calculated the spectrum from the shifts and coupling constants, and what was needed was the reverse calculation, shifts and coupling constants from the spectrum.

It was not at all obvious how to get the calculation to go in the opposite direction. The difficulty was centered in the diagonalization step; how could one find a recipe for finding the eigenvectors in the reverse direction? The only way we could see to do this was to guess at a set of shifts and coupling constants, calculate the spectrum, compare it with the experimental spectrum, change the shifts and coupling constants in what seemed like a reasonable direction to bring the calculated transition frequencies closer to the observed ones, and calculate again. One then repeated this until no better agreement could be obtained, or fatigue terminated the effort. The adjustments to the parameters, shifts, and coupling constants, were made by first order, i.e. if the observed separation between lines that looked like a doublet arising from spin-spin splitting was too large by 0.1 Hz, then J was reduced by 0.1 Hz. Satisfactory analyses of the spectra of propene, butene-1, and hexene-1 were obtained using this procedure.⁷

An improvement on this method of iterating was worked out by Delores Geisel. It would clearly be possible to make better corrections to the trial parameters if the change in line position caused by a change in parameter value $\Delta\nu_{ij}/\Delta\rho_m$ were available. Then the error in line position would be just the product of this differential and the correction to the parameter, ρ_m . To get the differentials, we calculated the trial spectrum and extra spectra with each parameter changed by a small amount. For each line, the finite differentials were calculated,

then corrections were applied using the least-squares criterion:

$$\begin{aligned} & (\Delta/\Delta\rho_m) \sum_l (\nu_{\text{obs}} - \nu_{\text{calc}})^2 \\ &= -2 \sum_l (\nu_{\text{obs}} - \nu_{\text{calc}}) (\Delta\nu_{\text{calc}}/\Delta\rho_m) = 0 \end{aligned} \quad (6)$$

In matrix notation, the equations which one wished to solve were the equations of condition

$$\mathbf{D}\Delta\mathbf{p} = \Delta\mathbf{v} \quad (7)$$

and the normal equations giving the least-square solution,

$$\mathbf{D}^T\mathbf{D}\Delta\mathbf{p} = \mathbf{D}^T\Delta\mathbf{v} \quad (8)$$

where $\mathbf{D}$ is the matrix of differentials, $\Delta\nu_{ij}/\Delta\rho_m$, $\mathbf{D}^T$ is its transpose, $\Delta\mathbf{p}$ is the desired vector of corrections to the parameters, and $\Delta\mathbf{v}$ is the vector of discrepancies in the line positions. Again, numerical methods for inverting real symmetric matrices, such as $\mathbf{D}^T\mathbf{D}$, were readily available, and the method was readily implemented. It worked quite well.⁸

There was one real difficulty with it. In order to evaluate the matrix $\mathbf{D}$, the computer produced a multicolumn output of frequencies, one column for each parameter varied. Occasionally, when a parameter was incremented, the frequencies of two lines would cross, so incorrect differentials would be generated. The only way to detect this was to sit with the multicolumn output and examine it, row by row, following the changes across the page, and identifying suspicious movements in the wrong direction or unusual changes in intensity. Using a pencil to connect the entries belonging to the same line generated a plot which looked like an array of mostly parallel but sometimes intertwined snakes. The kinks were removed by re-entering the frequencies in their correct positions. This experience impelled us to name the program LAOCOON, after the famous statue in the Vatican museum of the Trojan priest and his sons, Thymbraeus and Antiphas(!) attacked by serpents (Figure 1). We justified this name as an acronym for Least-squares Adjustment of Calculated On Observed NMR spectra.

Other groups had encountered and were attacking this problem as well. In 1960 Charles Reilly and Jerry Swalen reported an analysis of the spectra of some substituted epoxides, and described a systematic iterative method for correcting the trial parameters.⁹ The method involved applying the similarity transformation obtained in calculating the trial spectrum in the reverse direction to the set of energy levels deduced from the experimental spectrum.

Since the eigenvectors change more slowly than the Hamiltonian, this gave an improved trial Hamiltonian from which improved trial parameters could be obtained. The method worked well (although occasionally it did not converge), and they incorporated the method into a pair of programs, NMREN, which calculated the best fitting energy levels from the frequencies of an assigned experimental spectrum, and NMRT, which performed the iterative procedure improving the trial parameters.

Ragnar Hoffman very shortly¹⁰ also contributed the suggestion that the iteration could be performed by applying the similarity transformation in the forward direction to a small

Figure 1 Laocöon, reproduced with permission of the Vatican museum

correction Hamiltonian on the trial Hamiltonian, and applying perturbation theory to evaluate the correction Hamiltonian.

All of the methods above relied exclusively on matching the frequencies of the lines, and did not take account of the intensities. Intensities were useful in confirming the validity of the parameters in the trial spectrum, but since they could be measured with much less precision than the frequencies it was felt reasonable not to include them. Still, they were available, valid pieces of information, and Yoji Arata¹¹ in 1962 proposed a method in which they were included in the iterative scheme.

In 1962, our group was joined by Salvatore Castellano who had performed a prodigious task in analyzing the three-spin problem algebraically, while he was at MIT working with John Waugh.¹² There were several important insights that came out of this work. A very important one was the demonstration that the frequencies observed in a three-spin spectrum were often compatible with more than one set of shifts and coupling constants (quite aside from the trivial change of sign of all the coupling constants). This underscored the absolute necessity of setting trial parameters for iterative calculations which produced the correct assignment of all the transitions in the experimental spectrum. In a short time, he had written a computer program, EXAN, which used his analysis to obtain the possible sets of parameters directly from the transition frequencies in a three-spin spectrum, and this program was indispensable in the analysis of a variety of spectra such as the 3-fluoropropenes.¹³

One day in the spring of 1964 he came in with a piece of paper with these equations written on it:

$$\Lambda = e^{-1} \mathbf{H} e \quad (9)$$

$$\begin{aligned} \frac{\partial \Lambda}{\partial p_m} &= \frac{\partial e^{-1}}{\partial p_m} \mathbf{H} e + e^{-1} \frac{\partial \mathbf{H}}{\partial p_m} e + e^{-1} \mathbf{H} \frac{\partial e}{\partial p_m} \\ &= \frac{\partial e^{-1}}{\partial p_m} e \Lambda + e^{-1} \frac{\partial \mathbf{H}}{\partial p_m} e + \Lambda e^{-1} \frac{\partial e}{\partial p_m} \end{aligned} \quad (10)$$

He had found the way for getting the differentials exactly and had banished the snakes. As he pointed out, the matrix products $(\partial e^{-1}/\partial p_m)e$ and $e^{-1}(\partial e/\partial p_m)$ are skew symmetric (their sum is just $\partial e e^{-1}/\partial p_m$ or $\partial \mathbf{1}/\partial p_m$), and their products with Λ , which is itself diagonal, can only have zeros on the diagonal. Thus $\partial \Lambda/\partial p_m$ is equal to the diagonal elements of $e^{-1}(\partial \mathbf{H}/\partial p_m)e$. In addition, the differentials for the transitions ν_{kl} are just the differences $\partial \lambda_{kk}/\partial p_m - \partial \lambda_{ll}/\partial p_m$. Since e and e^{-1} are obtained in the diagonalization process, everything is available to get not just the finite differentials, but the exact differentials of all the transition frequencies.

When this process was built into LAOCOON, renamed LAOCOON II, it worked marvelously, and LAOCOON II and its descendants, LAOCOON III, LAOCN, and others became very widely used.¹⁴ It was also quickly improved and expanded in many ways: C. W. Haigh¹⁵ added the capability to handle groups of magnetically equivalent spins, and improved the efficiency in his program, LAME. He also improved the efficiency in calculating AB..XY.. type spectra by using factorization in his program LACX. Tom Flautt and his colleagues¹⁶ added the capability to include direct dipolar couplings in the Hamiltonian, so that spectra of molecules oriented in liquid crystals might be analyzed. Several groups, including ours, added the capability to include nuclei with spins greater than $\frac{1}{2}$, and to include quadrupole couplings in the Hamiltonian. An excellent version, incorporating many of the improvements, is PANIC, the program distributed by Bruker, Inc. A quite separate development was the series of DNMR programs, produced by Gerhard Binsch.¹⁷ These were aimed at the analysis of spectra from systems undergoing dynamic exchanges or rearrangements. DNMR2 and DNMR3 were simulation programs,¹⁸ allowing calculation in the forward direction, while DNMR5 was an iterative program,¹⁹ allowing refinement of the NMR and dynamic parameters, in the spirit of LAOCOON II.

In spite of the great success of these programs, and their very widespread and diverse applications, there remained one annoying problem. All of them (except EXAN) required the spectroscopist to produce an initial assignment or an initial guess at the NMR parameters which would lead to a calculated spectrum sufficiently resembling the observed spectrum that one could identify corresponding lines. For highly non-first-order spectra, this could be frustratingly difficult. That so many successful analyses were performed was a tribute to the ingenuity, dogged persistence, and luck, of the investigators. The first versions of LAOCOON went out to the users with the suggestion that the initial trial assignment might be obtained by 'shrewd guess, accident, divine inspiration, or examination of the entrails of freshly slain pigeons'. This recipe, patiently

followed, led to success in 99% of the cases we addressed, but occasionally even a prolonged and arduous effort failed to produce a recognizable match.

This problem was finally solved by Gerhard Binsch and David Stephenson²⁰ in 1980. Their program, DAVINS, accepts as input a digitized spectrum; both transition frequencies and intensities guide the program towards a final set of parameters. Falling into a local minimum and converging to an incorrect assignment and parameter set is avoided by an ingenious scheme which smooths the least-square surface to the extent that only one minimum exists. During the iteration, the smoothing is gradually reduced until the iteration is concluded with an unsmoothed surface. While convergence is not always achieved, trials indicate that it is successful in more than 90% of the cases, even with highly non-first-order spectra.

What of the present and the future? More powerful and comprehensive programs are being written at an accelerating pace—for simulation and analysis of 2D spectra, for simulation of spectra obtained during irradiation with rf, for simulation of spectra with the inclusion of relaxation processes. With the advent of ever faster, larger, and more versatile computers, there appears to be no limit on the reach and span of computer-aided analysis.

Bottomley, Paul A.: The Development of High-Field NMR Imaging: 0.12 T to 1.5 T

Paul A. Bottomley

GE Research and Development Center, Schenectady, NY, USA

In 1984 the Medical Systems Division of the General Electric Company (GEMS) in Milwaukee shipped six of its first NMR imaging product, a high-field, 1.5 Tesla (T), whole-body NMR system based on a prototype research scanner developed at the Corporate Research and Development Center (CRD) in Schenectady. The system represented a major advance over contemporary commercial offerings and existing whole-body research scanners: its field strength was about four or more times higher, its signal-to-noise ratio was better, and it uniquely combined NMR imaging and NMR spectroscopic capabilities in a single instrument. The system rapidly gained and dominated the market for high-performance NMR scanners, and nine years later, the total number of these systems shipped exceeded 1350.

Yet in the early 1980s whole body NMR imaging was not generally considered practical above about 10 MHz (~ 0.3 T) for two reasons: problems with rf penetration into the body,¹ and the inability to make high-frequency body rf coils.² I was partly to blame for the penetration argument, having published an earlier analysis while at Nottingham, showing significant penetration effects.³ That paper identified phase variation in the transmitted field as the main problem and suggested that the use of the 'power spectrum' would solve it, as it does. It did not rule out high-field imaging. The coil argument was based on the idea that phase variations must be kept minimal around the coil.² That idea didn't hold up for long: the standard solution is to allow a 2π phase variation around the coil.⁴ Anyway, at the time I thought the two arguments non-prohibitive. If the magnet existed and a coil could be made, I had no misgivings about attempting an imaging experiment, quietly.

I interviewed at CRD on April 30 1980. My first contact was with John Schenck who said they wanted to hire researchers for a whole body NMR program. I had been a research associate in Don Hollis's group at the Department of Physiological Chemistry at the Johns Hopkins Medical Institutions in Baltimore since 1978. I was trying to use imaging gradients to localize ^{31}P spectra within perfused hearts, but the group was disintegrating. Don Hollis had resigned, while the rest of us were supported by his grants. We had built a 3-cm aperture imager for an existing 180 MHz (4.1 T) spectrometer,⁵ the highest field imager at the time, but abandoned it in 1980 in favor of surface coils. These were new,⁶ and tuning them for the heart in those days involved groveling around the floor with a soldering iron, chip capacitors, and a heart beating sticky perfusate all over the place. I was doing just that on the afternoon of my interview, and tore off a sheet of spectra as I dashed for the plane.

I thought GE's interest was whole body imaging, so I focused my interview talk on NMR imaging work I had done

at Johns Hopkins and Nottingham.⁷ I was astounded to learn that their interest was localized spectroscopy. Red Redington, my future boss, wanted a whole body NMR system to study phosphate metabolism in people and their hearts. They could get no support from GEMS for NMR imaging, and so decided to pursue metabolism using corporate assessed funds. Years earlier, GE had concluded that NMR imaging could never compete with X-ray computed tomography in terms of signal-to-noise ratio per unit time. I produced the sheet of heart spectra and described our latest ^{31}P NMR experiments on regional ischemia⁸ with glee.

The day in August that I started at CRD, I sat in a meeting with Intermagnetics General Corporation. They, along with Oxford Instruments, were bidding for a high-field, high homogeneity, 1-m bore, whole body superconducting electromagnet for the spectroscopy project: neither had made one before. Oxford Instruments was ultimately chosen. The target field was 2 T but due to uncertainty about whether the design specifications could be met in practice, a minimum acceptable field was also set. This was 1.5 T.

In September, Bill Edelstein arrived from Aberdeen, equipped with the spin-warp NMR imaging method⁹ and experience from constructing a 0.04-T whole body imager. We exchanged stories of strife in our former Aberdeen and Nottingham laboratories. Bill offered: 'Well Paul, I'm not sure whether this spectroscopy thing is going to amount to anything, but if you want to work on that, I'd rather work on NMR imaging'. I responded 'I don't know whether spectroscopy is going anywhere either, but I certainly believe that it is imaging that is more likely to succeed'.

The 1.5–2 T magnet wasn't due until late 1981 or 1982. Bill and I sat in a succession of temporary offices for a month or two waiting for someone to tell us what to do (not that we'd do it, anyway). Nothing happened, so we decided to build a low-field imaging system. We knew we'd need imaging technology for localized spectroscopy anyway. Red got \$100K from GEMS to buy a 0.12-T resistive electromagnet. We'd build and ship this system to the Hospital of the University of Pennsylvania (HUP) for patient studies before the high-field system came. The group at this time comprised Bill Edelstein and myself full-time, and Bill Leue, Howard Hart, and John Schenck part-time, managed by Red. I did the gradient and rf coils, and put together bits of the rf spectrometer. We had images for the October 1981 NMR imaging meeting in Winston-Salem,¹⁰ which I recall as the all-time best NMR meeting for innovations per unit time. The 0.12-T system went to HUP in August 1982.

By early 1982, at last, GEMS had become concerned about the rise of NMR imaging and its potential impact on its X-ray CT product. 'Luminary' customers were looking elsewhere to purchase NMR systems, and GEMS had nothing on NMR at their all-important technical exhibit at the Radiological Society of North America (RSNA) meeting in Chicago in December 1981. This was in the face of major exhibits by Picker-EMI, Technicare, Siemens, Philips, and some smaller companies. GEMS reversed strategies and asked us to turn down our high-field magnet for a 'short' spate of imaging. I figured I could make an NMR coil set that worked at about 20 MHz, and had a body coil in March. The plan then was to obtain a few spectra at high field when the magnet arrived, then turn it down to 0.5 T. This was presented at a meeting with GEMS on April

7. Meanwhile GEMS was also seriously considering offering a commercial resistive system like our 0.12-T one.

The high-field magnet was installed by the end of May 1982. It barely made it to 1.5 T and was reluctant to stay there: its field drifted down at a rate of about 2 ppm h⁻¹. Sometime thereafter I made a head imaging coil which worked at 54 MHz. Very excited, I showed Red: 'Looks like we won't have to turn the field down, after all'. I was concerned that once the field came down, given the way imaging was hotting up, it would never go up again. I was affronted when my suggestion was transformed into a command from on high a week or so later: 'Thou shalt make images at 1.5 T'.

GEMS, increasingly anxious over imaging, foisted an extra manager on us, and a team of program planners who descended in July to make us make images more quickly. They came to make charts with boxes of tasks with surrealistic completion dates. We were interrogated for hours but I divulged nothing: 'It'll be done when it's done'. Finally, Red got fed up with the fuss and threw them out. I took over the NMR coils and spectrometer with help from L. S. Smith and O. Mueller. John Schenck with Bill Edelstein came up with new distributed current gradient coils. Bill Leue did the computer and interface, and Howard Hart looked after the magnet.

By October I had a head saddle coil that self-resonated at 86 MHz and a slotted-tube resonator that would work at 1.5 T. I acquired surface coil ³¹P spectra of metabolites in the legs, head, and torso. During this period, Bill Edelstein and I were also regular trippers to HUP, to maintain the 0.12-T system. Finally, late in the evening of November 22, Howard Hart and John Schenck made the first 1.5-T images of the head and limbs using the saddle coil.

The image quality and resolution of these images wasn't good. We had one week before the 1982 RSNA meeting to do better, but our 5-kW rf power amplifier was broken. Red had one flown in from GEMS. We were walking back from lunch the day it arrived: the crowd outside the NMR building was ominous. There was the power amplifier, all right, stuck in the magnet! It had apparently taken off while being wheeled too close: the mover was in hospital with hand injuries. We tried winching it out, but the Dewar broke: the magnet turned into a snowball, and we were wiped out until the end of January (Figure 1). GEMS ran with the images and spectra that we had, however, printing green leaflets announcing our high-field imaging/spectroscopy capability as a breakthrough at the 1982 RSNA meeting. This generated a storm of interest, and undoubtedly stalled many NMR purchases to await GEMS's offering, as was hoped.

Late on February 1, 1983 with the magnet fixed and Howard's head inside the slotted tube resonator, I began obtaining fantastic images with 256 × 256 resolution in 4-mm slices and 100 s scan times. I was ecstatic. My notebook that day is scrawled with expletives next to the polaroid prints. There was no one to show (Howard was magnet-bound). I dragged in the cleaner: 'Isn't this the most incredible picture you've ever seen?' We published in the *Lancet*.¹¹ We knew the images were better than anything else around at the time.

GEMS's competitors were committed to low-field systems and some ugly accusations flew amongst marketeers: 'they faked the pictures', 'they can't do whole body imaging', 'the increased rf power is hazardous', 'their work was rejected as unscientific'. The most vocal were from the Radiologic Imaging Laboratory in South San Francisco who claimed

Figure 1 The 5 kW rf power amplifier, complete with dolly cart, being winched from the bore of the whole-body 1.5-T imaging system, at full field in November 1982 (picture courtesy W. A. Edelstein)

that the signal-to-noise ratio decreased above 0.3 T and that the switch-over time between imaging and spectroscopy was 2–14 h.¹² We hunkered down: Bill Edelstein made a 1.5-T body coil and started getting body images in March.¹³ The forces faced-off at the meeting in August 1983 of the Society of Magnetic Resonance in Medicine in San Francisco. Bill's retort at the session paraphrased a song: 'If you don't have the field you love, you love the field you have'. For my part, GEMS gave me a scrapper award, 'for ultimate defense of high-field strength'.

Bovey, Frank A.: NMR of Polymers

Frank A. Bovey

AT&T Bell Laboratories, Murray Hill, NJ, USA

When polymers in solution were first observed by high-resolution NMR some 30 years ago, almost nothing was known about the subject. Previous work at Bell Laboratories, by D. W. McCall and W. P. Slichter,¹ had been confined to the solid state. Proton resonances were too broad to reveal any structural information and it was primarily *chain motion* that was of interest. There was in fact somewhat the same feeling about solution spectra as about solid state spectra — namely, that they would be too broad and too complicated to be of any interest for the determination of structure. Happily, when the experiment was actually tried this proved not to be the case, and the rest is history.

The chemical shifts and proton *J* couplings of random coil macromolecules are closely similar to those of small molecules of analogous structure. In Figure 1 the spectrum of ethyl orthoformate (1) is compared with that of poly(vinyl ethyl ether) (2).

Figure 1 60 MHz ¹H NMR spectra of (a) ethyl orthoformate and (b) poly(vinyl ethyl ether)

The polymer exhibits the same ethyl proton resonances and, in addition, those of the main chain β -protons, appearing at 1.5 ppm, and of the α -protons, appearing under the CH₂ quartet. The broadening of the polymer lines is in part due to the slower motions of the large molecules but is mainly due to overlapping resonances arising from steric sequences (*vide infra*). In general, linewidth is only weakly dependent on molecular weight or the macroscopic viscosity of polymer solutions.

NMR is very informative concerning the stereochemical configuration of vinyl and diene polymer chains. In Figure 2 are shown 500 MHz proton spectra of (a) syndiotactic and (b) isotactic poly(methyl methacrylate). Polymer (a) was prepared with a free-radical initiator and polymer (b) with fluorenyllithium in toluene, an anionic initiator. To interpret these spectra let us consider the chain in terms of sequences of two monomer units or *dyads*. There are two possible types of dyads and they have different symmetry properties. The syndiotactic or racemic (*r*) dyad has a twofold axis of symmetry and consequently the two methylene protons are in equivalent environments on a time average over the chain conformations, which are not necessarily in the planar zigzag form shown in the projection formulas (3) and (4). These protons therefore have the same chemical shift and appear as a singlet despite strong two-bond or geminal coupling between them. The isotactic or *meso* (*m*) dyad has a plane of symmetry but no twofold axis and so the two protons are nonequivalent and have different chemical shifts. When there is no vicinal coupling to neighboring protons, as is the case in poly(methyl methacrylate), the syndiotactic sequences should exhibit a methylene singlet while the isotactic form should give two doublets, each with a spacing equal to the geminal coupling, ca. 15 Hz. We see in Figure 2 that the methylene spectrum of the anionic polymer (b) is almost exclusively a pair of doublets (ca. 1.6 and 2.3 ppm); quantitative assessment shows that this polymer is 95% isotactic. The methylene spectrum of the free-radical polymer (a) is more complex, but the principal resonance (at ca. 1.9 ppm) is a singlet, showing that this polymer is predominantly syndiotactic but more irregular than (b). This is generally the case for vinyl polymers prepared with free-radical initiators. (The other resonances are discussed below.)

We see that proton NMR can provide absolute stereochemical information concerning polymer chains without recourse to X-ray or other methods. Somewhat more detailed, but not absolute, information can be gained from the methyl proton resonances near 1.2 ppm. (The ester methyl resonances at ca. 3.6 ppm, which are not shown, are less sensitive to stereochemistry.) In both spectra we note three peaks—or, more correctly, groups of peaks (*vide infra*)—appearing in similar positions but with greatly different intensities. These correspond to the α -methyl groups in the center monomer unit of the three possible triad sequences: isotactic (5), syndiotactic (6), and heterotactic (7). These may be more simply and

Figure 2 500MHz ^1H NMR spectra of (a) syndiotactic and (b) isotactic poly(methyl methacrylate)

appropriately designated by the m and r terminology, as indicated. Measurement of the relative intensities of the mm , mr , and $rr\alpha$ -methyl peaks, which appear from left to right in both spectra in this order, gives a valid statistical representation of the structure of each polymer.

From the triad data one may gain considerable insight into the mechanism of propagation. This is one of the principal uses

Figure 3 Probabilities of various triads formed in a Bernoulli propagation process

of such information. Let us designate by P_m the probability that the polymer chain will add a monomer unit to give the same configuration as that of the last unit at its growing end, i.e. that an m dyad will be generated. We assume that P_m is independent of the stereochemical configuration of the growing chain. The generation of the chain is a Bernoulli-trial process; it is like reaching into a large jar of balls marked m and r and withdrawing a ball at random. The proportion of m balls in the jar is P_m . Since two monomer additions are required to form a triad sequence, it is readily evident that the probabilities of their formation are

$$[mm] = P_m^2 \quad (1)$$

$$[mr] = 2P_m(1 - P_m) \quad (2)$$

$$[rr] = (1 - P_m)^2 \quad (3)$$

The heterotactic sequence must be given double weighting because both directions mr and rm —observationally indistinguishable—must be counted. A plot of these relationships is shown in Figure 3. It will be noted that the proportion of mr (heterotactic) units rises to a maximum when P_m is 0.5, corresponding to a strictly random or atactic configuration for which $[mm]/[mr]/[rr]$ will be 1:2:1. For any polymer, if Bernoullian, the $[mm]$, $[mr]$, and $[rr]$ sequence intensities will lie on a single vertical line in Figure 3, corresponding to a single value of P_m . Spectrum (a) in Figure 2 corresponds to these simple statistics, P_m being 0.25 ± 0.01 . The polymer corresponding to spectrum (b) does not. The propagation statistics in this case can be interpreted to indicate that the probability of isotactic placement is dependent upon the stereochemical configuration of the growing chain and cannot properly be expressed by a single parameter such as P_m . Free radical and

Table 1 Stereoregular Sequences in Poly(Methyl Methacrylate)

	Designation	α Substituent projection	Bernoullian probability		Designation	β -CH ₂ projection	Bernoullian probability

	<i>mmmr</i>		$2P_m^3(1 - P_m)$		<i>rmr</i>		$P_m(1 - P_m)^2$
	<i>rmmr</i>		$P_m^2(1 - P_m)^2$		<i>mrmm</i>		$P_m^2(1 - P_m)$
	<i>mmrm</i>		$2P_m^3(1 - P_m)$		<i>rrm</i>		$2P_m(1 - P_m)^2$
	<i>mmrr</i>		$2P_m^2(1 - P_m)^2$		<i>rrr</i>		$(1 - P_m)^3$
	<i>rmrm</i> (heterotactic)		$2P_m^2(1 - P_m)^2$				
	<i>rmrr</i>		$2P_m(1 - P_m)^3$				
	<i>mrrm</i>		$P_m^2(1 - P_m)^2$				
	<i>rrrm</i>		$2P_m(1 - P_m)^3$				
	<i>rrrr</i> (syndiotactic)		$(1 - P_m)^4$				

cationic propagations always give predominantly syndiotactic chains. Anionic initiators may also do so if strongly complexing ether solvents such as dioxane or glycol dimethyl ether are employed rather than hydrocarbon solvents as with the polymer depicted in Figure 2(b).

It is evident that in the spectra of Figure 2, there is fine structure in both the methylene and methyl regions which we have not discussed. In spectrum (a) this corresponds principally to residual resonances of the stereoirregular portions of the chains; in (b) such residual resonances are less conspicuous. These arise from sensitivity to longer stereochemical sequences than dyad and triad. In Table 1 are shown planar zigzag projections of such sequences, together with their frequency of occurrence as a function of P_m , assuming Bernoullian propagation. The tetrads, and all 'even-ads', refer to observations of β -methylene protons (or β -carbons), while the 'odd-ads' refer to substituents on the α -carbons (or α -carbons themselves). Resonances for tetrad sequences or higher 'even-ads' should appear as fine structure

in the dyad spectra, while pentad sequences or higher 'odd-ads' should appear as fine structure on the triad resonances.

It may be noted that *r*-centered tetrads, e.g. *mrr*, do not necessarily appear as singlets if the sequence as a whole lacks a twofold axis.

The numbers of observationally distinguishable configurational sequences, or *n*-ads, designated $N(n)$, obey the following relationship

$$\begin{array}{cccccccccc} n & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ N(n) & 2 & 3 & 6 & 10 & 20 & 36 & 72 & 136 \end{array}$$

or in general

$$N(n) = 2^{n-2} + 2^{m-1} \quad (4)$$

where $m = n/2$ if n is even and $m = (n - 1)$ if n is odd. Discrimination of these longer sequences is unlikely to be possible beyond $n = 6$ (hexads) or $n = 7$ (heptads). The

Figure 4 ^1H 2D COSY spectrum at 500 MHz of poly(methyl methacrylate)

observation of such sequences permits rather searching tests of polymerization mechanisms.

Let us now observe isotactic poly(methyl methacrylate) in the 2D proton NMR mode, also at 500 MHz. The spectrum shown in Figure 4 is an example of correlated 2D NMR, in which the correlation is provided by J coupling. Along the diagonal is the 1D spectrum in contour form. This of itself provides no new information, but the off-diagonal resonances or cross peaks connect J -coupled protons. This supplies the

whole network of connectivities at a glance. In the present case the crosspeaks confirm the geminal coupling in the *meso* methylene dyads. The methylene proton which projects on the same side of the planar zigzag as the ester groups in the *trans-trans* conformation is designated as *erythro*, the other being *threo*. Rather unexpectedly, we see a cross peak between the α -methyl resonance and the *erythro* methylene proton but not the *threo* proton. This correlation is brought about by very weak four-bond couplings of the order of 1 Hz and tells us that the preferred conformation of the isotactic chain is *trans-trans*. In this conformation only the *erythro* proton is capable of forming with an α -methyl proton (one-third of the time for each) a 'W'-shaped four-bond path of the kind generally thought to be favorable for such long-range coupling. Expressed somewhat differently, the methyl group and the *erythro* proton exhibit in the *trans-trans* conformation the 180° dihedral angle corresponding to maximum coupling according to the correlation of Barfield, whereas the *threo* proton is near a minimum. This correlation is also observed for methyl methacrylate oligomers and is in agreement with energy calculations indicating a strong *trans* preference.

Brey, Wallace S.: The First 40 Years Should Be the Hardest

Wallace S. Brey

University of Florida, Gainesville, FL, USA

MY INTRODUCTION TO NMR

My first contact with nuclear magnetic resonance came in the year 1951–52. The Philadelphia Section of the American Chemical Society sponsored several series of Continuing Education lectures for chemists, and one of these series, arranged by Adalbert Farkas, was devoted to heterogeneous catalysis. Not only did I help to manage these programs, but my industrial experience and doctoral research at the University of Pennsylvania had been in this field. One of the lecturers was P. W. Selwood, who described some of the extensive studies he had made of the magnetic susceptibilities of supported metal catalysts, the results of which were taken as a measure of the extent to which the metal atoms were dispersed over the surface rather than aggregated into clumps. Indeed, during my earlier graduate days at Penn, I had participated in a physical chemistry seminar in which we worked through Selwood's newly published book.

During the course of his talk, Selwood did not mention NMR, but at the beginning of the question period there was a great deal of excitement among a number of the members of the audience who were chemists employed in the petroleum industry. They wanted to know 'the story about all this business of looking at protons', of which they had heard rumors. Selwood obliged with a 20-min introduction to NMR, representing the precessing and flipping nuclei with a long pointer conveniently at hand. The questioners were referring to what was probably the first application of NMR to heterogeneous catalysis. Selwood had sent one of his students to use the NMR apparatus at Harvard to investigate the effects of paramagnetic catalyst systems on the relaxation times of organic liquids in which they were immersed,^{1,2} and the results for the amount of exposed metal surface were consistent with the results from susceptibility measurements.

Two more associations with NMR occurred after I moved to the University of Florida in 1952. One was a Sigma Xi tour lecture by Felix Bloch, devoted to the principles of NMR and a few of the early applications. The second was in 1954 at an instrument exposition at the Commercial Museum, adjacent to Convention Hall in Philadelphia, which I attended on the way to an ACS meeting in New York City. Each registrant was able to choose two from a list of instrument types, one for the morning and one for the afternoon. Some eight or so sections were curtained off in the exhibit hall and each was assigned to an instrument manufacturer. I attended the General Electric session on mass spectrometry, but my real interest lay in the Varian session on NMR.

The Varian representatives had set up an operating spectrometer. The magnet was of course an electromagnet, with a

field strength corresponding, as well as I can recall, to 30 MHz. The item of great pride on the part of the Varian representatives was the introduction of sample spinning, which enabled the quartet–triplet structure in the spectrum of ethanol, displayed on a small round oscilloscope screen, to be resolved.

As I look back, I am still amazed at the quality of the Varian staff who participated in this session: they were the people responsible at the highest level for the design of the instrument. Most impressive was the presence of one of the Varian brothers himself, a person most striking in physical appearance. During the course of the lectures, attention was turned away from the instrument for some time, and then someone noticed that the spectrum has disappeared from the screen—as one might expect, considering the rise in temperature in a confined space, for a spectrometer without a lock. In an instant, three or four of the 'inventors' of NMR instrumentation converged on the console, reaching for the switches that would reverse the field drift.

NMR SPECTROMETERS IN THE UNIVERSITY OF FLORIDA DEPARTMENT OF CHEMISTRY

In 1958, Harry H. Sisler, Chairman of the Department, convinced of the power of NMR as a tool in chemistry, collected money from various pockets to purchase a spectrometer and I was put in charge, partly because I shared with Arthur M. Buswell, earlier a pioneer in the use of infrared spectroscopy, an NIH grant on water structure. One of the most significant applications of this instrument was in the structural analysis of fluorinated organic compounds produced by the half dozen research groups active in this area for a period of years at the University of Florida.

The Varian DP-60 (for 'dual-purpose 60 MHz') spectrometer was operated in field sweep mode, with a fixed frequency for each nucleus, controlled by a crystal oscillator. Our instrument was among the first to be manufactured. There was no lock, and the way one determined peak positions accurately was to sweep the field back and forth 5 to 10 times, with audiofrequency sidebands applied, tediously measure relative distances on the continuous chart paper, and average the results. Initially, the magnet had no shim coils. The procedure for optimizing homogeneity was to 'squeeze' the magnet yoke with a ratcheted screw working against a metal flange attached to the magnet support and to move the probe around near the middle of the field to find, by trial and error, the best location. Further, when the magnet was first brought up to field, it was necessary to 'overcycle' it, raising the field by a definite amount above the operating value and then lowering it. This served to reduce the domed contour of the field near the magnet axis. This system did have a 'Superstabilizer', a galvanometer with optical beam falling between two photocells arranged to compensate for transients in the magnetic field.

Very soon *x*, *y*, *z*, and radial shims were added to the magnet, along with insulation about the yoke to reduce the temperature variation. The magnet was cooled by tap water circulating through copper tubing wound along with the conductors. After a few years, this small tubing was blocked up and the magnet could only be operated at reduced field—nice proton spectra at 15 or even 24 MHz could be obtained. Despite valiant efforts by relays of students pouring

phosphoric acid solution into the coils, they remained blocked and were eventually replaced, along with the addition of a heat exchanger.

Early studies on recalcitrant nuclei, such as carbon-13, were based on fast passage, dispersion mode resonances, which do not saturate. A neat sample of low molecular weight material at natural isotopic abundance gives a satisfactory resonance under these conditions, permitting evaluation of the chemical shift.

Our research interests in the structure of liquids containing fluorocarbons, the binding of substrates to catalysts, and the hydration of proteins led to the use of relaxation rate measurements. At first these were done by a combination of saturation studies for T_1 and linewidth determinations for T_2 . Later a set-up based on pulses was assembled by Vincent Heuring by combining a series of Tektronix pulse generator units. In the surface studies, the wideline function of the dual-purpose spectrometer was extremely useful. The hardware was essentially the same as that in Varian EPR units and comprised a motor-driven field-scanning mechanism and a source of modulation of the field at variable intensity and at a selected frequency. The sensitivity of this scheme was very good, but care had to be exercised to adjust the modulation level for the linewidth of the resonance. For example, when we first followed the linewidth variation for protons in adsorbed methanol to temperatures well below room temperature, it appeared that the line first widened and then narrowed as -90°C was approached. A little reflection led to the realization that the resonance of the hydroxyl proton was continuing to broaden as the temperature was lowered, becoming so broad that the modulation was not covering a wide enough field to pick up the peak with reasonable sensitivity, and that only the somewhat narrower resonance of the methyl group was evident at low temperatures.

In the mid-1960s, the Department acquired two A-60 spectrometers, along with a 'computer of average transients', better known as a CAT. The latter could be used with the DP-60 and with EPR instruments as well as with the A-60s to enhance sensitivity. In 1968, matching grants enabled us to acquire a 100 MHz instrument. The first unit was a DA-100 with 12-in. vertical yoke, iron magnet. The magnet was shortly replaced by a 15-in. magnet with tilted yoke, giving access to the samples from directly above. The power supply for this magnet was based upon a mechanically driven set of brushes in a variable transformer set-up. These soon began to arc and the supply was replaced, just as the warranty period expired, by an electronically regulated supply. Multinuclear capability was provided by new probes along with the retuning of several rf units from the DP-60.

An interesting sidelight to the acquisition of this spectrometer is related to my visit to Palo Alto to inspect the available equipment. I was proudly shown, among other items, Ray Freeman's set-up for measuring relaxation times which had been christened the 'Freelaxer'. The magnet for this instrument was enclosed in both an inner and an outer housing of transparent plastic, and was equipped with a two-stage field stabilization circuit. There was also a pulse sequence generator, prearranged to give the proper sequences for various types of measurement. After I was filled with the best Palo Alto Chinese food, I was taken by Martin Packard in his Packard convertible to his house on the hills with a wonderful view overlooking the bay. The conversation there led to questions

about my views on the future of NMR, the most specific of which was whether there was likely to develop any general interest in the determination of relaxation times, to which I answered bravely an emphatic 'Yes!' However, before the Freelaxer could reach commercial production, pulsed FT NMR appeared on the horizon.

The HA-100 console was traded in for an XL-100 in 1970. Again, our instrument happened to be among the first dozen produced. All the components arrived just in time for the 12th ENC at Gainesville in 1971, the first ENC to be held away from Pittsburgh. This instrument had a fully equipped decoupler module, enabling irradiation at any frequency over an extremely wide range, and its 12-mm probes afforded high sensitivity for less receptive nuclei, although observation was limited to hydrogen, fluorine, phosphorus, boron, and carbon. The output of the decoupler was not nearly sufficient to decouple fluorines over the range of some 100 ppm, but applied between acquisitions, the rf provided a very useful Overhauser sensitivity enhancement for observation of ^{13}C . There was also an external lock, particularly useful for studying very reactive fluorinated molecules in sealed tubes.

The design of the XL-100 console was rather interesting because there were on the back quite a few connectors of high pin count which had no apparent function. It developed that the designers had foreseen the application of computers and had provided these for digital inputs to control the decoupler and observe offset frequencies, a function which became somewhat superfluous with pulsed FT methods. In 1978, the addition of a Nicolet multinuclear unit incorporating a PTS synthesizer and provided with an 18-mm probe for low frequencies greatly increased the versatility of this instrument, permitting, for example, acquisition of ^{43}Ca spectra in natural abundance.

An NT-300 system with wide bore Oxford magnet was delivered in 1981. At this stage of development, designers avoided multinuclear decoupling and concentrated on proton irradiation, a situation unfortunate for the study of ^{13}C in fluorocarbons. This system was subsequently upgraded with a Phoenix disk drive, a coprocessor board for the computer, and a raster-scan monitor. Probes include a custom-made Jakobsen solid state MAS probe.

SOME CONTRIBUTIONS FROM THE FLORIDA LABORATORY

Several of the more significant contributions from students in the NMR research group at the University of Florida may be mentioned. K. C. Ramey found very interesting behavior of the coupling constants between fluorine nuclei as the temperature was lowered to below -90°C .³ In a similar vein, K. D. Lawson showed that wideline results for alcohols absorbed on thorium oxide reflected successive freezing out of the mobility of various molecular units as the temperature is lowered.⁴

M. E. Fuller showed that the activation energies for the motion of water molecules bound to solid proteins pass through a minimum at about the amount of water equivalent to one molecule per polar functional group.⁵ In collaboration with Hans Jakobsen of the University of Aarhus, L. W. Jaques and P. J. Kanyha extended selective polarization transfer methods and applied them to the determination of the signs of coupling constants.^{6,7}

Much of our work has been devoted to the study of fluorinated molecules. In addition to spectra of new compounds synthesized within the university, many thousands of spectra were run for products of Peninsular ChemResearch, now PCR, Inc. Perhaps the most interesting of the latter were those concerned with the development of the production process for 5-fluorouracil by a direct fluorination procedure, rather than by a complex, highly expensive multistep synthesis. In the days before NMR spectrometers were so universally available, we also ran samples for a group from Dewey and Almy Chemical Co., in a project to develop a safer fluorinated anesthetic, and for Air Products and Chemicals. We still provide NMR service for the fluorine chemists in the Air Force Laboratories at Dayton, Ohio.

With the widespread application of multidimensional experiments, we can look back on what were possibly the first three-dimensional experiments to be reported, in which COSY and *J*-resolved segments were combined.⁸ Michael Cockman did the programming required to keep track of scale factors and other details during the processing and he and H. Daniel Plant carried out the experiments using a Hawk disk drive which required a series of cartridge withdrawals and insertions to do all the processing.

THE JOURNAL OF MAGNETIC RESONANCE

About 1964, I received a call from an editor at Academic Press, who stated that he was taking a poll to find out whether it was the feeling of NMR scientists that a journal devoted to the field was needed. The answer was no and I thought nothing more about the matter for several years. In 1968, my answer changed to yes when I was asked a similar question. A bit later, Thomas Lanigan of Academic Press called and asked to arrange to meet me at an American Chemical Society meeting in Atlanta. The gravity of his voice led me to suspect what the subject of the meetings was to be, and I was ready with a positive answer when he suggested that I undertake the editorship of the new journal.

We did not know that another periodical devoted to NMR was being planned in England at the same time. Although the original idea of the Academic Press editors was related to the increased use of NMR in organic chemistry, I was, fortunately, given complete freedom by the publishers to define the scope of the *Journal* and so it was made very broad, including all aspects of magnetic resonance, for all phases of matter, all types of nuclei as well as electrons, and encompassing both theoretical and practical points of view.

At the beginning of publication, from 1969 on, the pages of the *Journal* were composed and printed in Britain because of economic reasons, and copies intended for North America were flown across the Atlantic in bulk and mailed from New York. Considerable difficulty resulted when the compositor decided to convert to computerized typesetting and underestimated by a large margin the time required for the transition. Consequently, the *Journal* dropped several months behind publication schedule until these difficulties were finally overcome.

Throughout the ensuing years, there has been a steady expansion in the number of manuscripts submitted, and the number of pages published per year has been correspondingly increased. In 1991, it became evident that the amount of material concerning biological applications was increasing so rapidly that difficulty in accommodating all the significant papers could be anticipated. Consequently, in 1993, a separate series of the *Journal* was begun in which this area is emphasized.

DEDICATION

In view of the critical role that computers have played in the development of modern NMR, it is appropriate to conclude with an acknowledgment, of both a professional and personal nature, to John W. Mauchley who conceived and built the first operating electronic digital computer. I had the great pleasure and benefit of working with him as an undergraduate assistant at Ursinus College, and the honor of having my contributions cited in two of his publications. Most of what I know about the physics on which NMR techniques are based derives from his teaching in lectures or his personal instruction in the laboratory.

Budinger, Thomas F.: Perspectives on Reconstruction Tomography and Magnetic Field Physiological Effects

Thomas F. Budinger

University of California, Berkeley, CA, USA

The inverse problem of determining in three dimensions a process or constitutive property of matter by multiple observations from different angles had its practical applications in geophysics, astrophysics, and biological molecule structural analysis long before magnetic resonance was discovered as a method of probing the state of matter. The ideas of back projection into a 'smoke filled' a posteriori space were used by crystallographers in the mid-1900s, with the first practical back projection images performed by Kuhl and Edwards in nuclear medicine applications in 1963 and the first Fourier projection theorem reconstruction of phage tail structure by deRosier and Klug in 1968. One of the simplest approaches to reconstruction was undertaken in 1956 by myself for the problem of determining iceberg shape and volumes using sextant, compass, and radar. Ronald Bracewell advanced astrophysics through Fourier techniques in the 1970s. By 1974 we had succeeded in overcoming the 'intractable mathematical problem' of the attenuated radon transform by incorporating a priori information regarding the variable attenuation coefficient in the emission tomography problem.¹ This work caught the attention of Paul Lauterbur with whom I have worked since. At the same time Peter Mansfield sent me a manuscript on echo planar reconstruction mathematics which I found fascinating but a challenge to understand well enough to teach until a few years later. Through the encounters with these two great innovators and the galley proofs of Kumar, Welti, and Ernst's seminal paper, which Raymond Damadian asked me to explain to him, I became interested in the problem of magnetic resonance applications to the study of the human body.

Because my interest in brain stimulation by electric and oscillating magnetic fields was known to Paul Lauterbur, he asked me to analyze the effects of the magnetic resonance experiment on human physiology. The deadline for the analysis was June 1979 for an IEEE conference. So I squeezed literature, good and bad, and my own experiments with some cautious predictions² which were reiterated a few years later in an expanded paper in 1991.³ During the last 20 years of advancement in magnetic resonance imaging of human subjects the fears of health effects have been expressed in scientific debate ranging from a chaired professor at the University of Pennsylvania saying that one day my 'brain might click off while walking down the street' to predictions that blood flow will be seriously retarded in high (e.g. 4T) fields. None of these predictions is of concern now.

During this last 20 years, however, the hunt for effects on human physiology has ranged from evaluation of 40 T static field exposure of a musician's hands for years at the MIT Francis Bitter Magnet Laboratory to oscillating magnetic field exposure at various frequencies from 3000 T s⁻¹ in animals to 100 T s⁻¹ in man, in Germany. The search for rf heating effects has ranged from evaluation of hyperthermia physiology of human exposures to 42.5 °C in experiments by me with Robert Pettigrew and by me in Scotland to actual measurements of energy absorption in humans undergoing MRI protocols by swallowed and even surgically implanted probes in Ohio using pulse sequences which challenged 1986 vintage rf amplifiers. Fortunately, the power at 50–60 Hz around the contemporary NMR environment is low and we avoided the power-line electromagnetic field hysteria of the early 1990s.

The reason so much effort was placed on the measurement of physiological effects of static and oscillating magnetic fields is that advances in magnetic resonance applications to medical science depend on improvements in temporal and spatial resolution as well as improvement in signal-to-noise, particularly for carbon-13, sodium-23, potassium-39, nitrogen-15, and even chlorine and rubidium. Applications depend on rapidly switching magnetic fields and increases in static fields beyond 4 T. Known effects are neuromuscular stimulation from *E*-fields induced by rapidly oscillating magnetic fields of 60 T s⁻¹ at 1 kHz and body heating associated with rf power deposition.

Goals such as human cortex 3D isotropic imaging at 300 μm resolution and short *T*₂ potassium concentration studies in 8 cm³ volumes are possible and can be safely accomplished at fields beyond 4 T. These are only two of a multitude of safe projections which lead to the prediction that this methodology will provide fundamental knowledge on the biochemical bases of mental and behavioral disorders, as well as knowledge on the mechanisms of cancer, atherosclerosis, and aging.

Bydder, Graeme M.: Magnetic Resonance at Hammersmith Hospital

Graeme M. Bydder

*Hammersmith Hospital, Royal Postgraduate Medical School,
University of London, London, UK*

When I joined the EMI-Hammersmith NMR imaging group on 1 January 1981 the prospects appeared exciting. The world's first cryomagnetic-based magnetic resonance system had been installed just before Christmas 1980 and was already producing images. It was the first such system to be placed inside a hospital and patients' studies were eagerly awaited. The group was well aware that the first X-ray computed tomography (CT) scan of a patient performed at Atkinson-Morley's Hospital on 1 September 1971 had shown a left frontal lobe tumor. This had been such a remarkable event that immediately following it those most reserved of men, James Ambrose and Godfrey Hounsfield, had jumped up and down like football players who had just scored a winning goal.¹ The success of the technique had seemed assured from that point on. Likewise, using the first commercial body CT scanner, Louis Kreel at Northwick Park Hospital had diagnosed a cancer of the pancreas in the first patient examined on 1 July 1975. Body CT had also gone on to become a great success.

There were a number of problems with NMR imaging though. Although Godfrey Hounsfield had received the Nobel Prize for CT in 1979, Electrical and Musical Industries Ltd, (EMI) had since moved out of medical imaging. They had sold their interests in CT and were looking for a buyer for their NMR imaging research group. There were also difficulties between the EMI team and the Hammersmith Hospital group. The Department of Health, which had helped fund the construction of the NMR imaging system, was in effect using the hospital group to test whether or not the system met its specifications. From the EMI research team's point of view the hospital group was perceived as people who did not help with the development of the system but criticized it to one of their principal paymasters.

There were other difficulties. The Department of Radiology was not only installing a new NMR system but also a CT system and there was no radiologist in the department with any clinical experience with either technique. The new CT system was bought from a rival company (Siemens) and was providing very high quality images of greater spatial resolution than the NMR system. The NMR machine itself was single slice only, and each of these slices took 7 min to reconstruct (the CT system took only 5 s). It was difficult to see how it would be possible to complete even a single examination of the head (16 slices) with NMR in less than 3 h. The patient handling of the NMR system was acutely uncomfortable, the water-cooled valve amplifiers were highly unreliable, and the sole copy of the operating manual went missing soon after installation and was never found again.

Patient studies began on 25 March 1981 and, unlike the situation with both head and body CT, the diagnosis was missed in each of the first three cases studied (multiple sclerosis, hemosiderosis, and a posterior fossa lesion). Soon

after, the clinical director of NMR research, Professor Frank Doyle, suffered a major stroke which left him severely aphasic and hemiplegic. The Hammersmith Hospital physicist left, and so did the visiting professor from Yale who had been advising on the project. This left the hospital group with only two people. On the clinical side it soon became apparent that Hammersmith Hospital, which had no neurosurgery and very little neurology, was in no position to supply suitable patients for clinical evaluation of NMR imaging in neurological disease.

We also knew that the Nottingham clinical group headed by Brian Worthington had published the first series of brain patients in September 1980² and had received over 1000 reprint requests. Frank Smith in Aberdeen was energetically studying patients and had published results in both the *British Medical Journal*³ and the *Lancet*.⁴ We also knew that the San Francisco group (headed by Larry Crooks and Leon Kaufman) had published animal studies and were due to receive the next whole body cryomagnet from Oxford Instruments after ours. They were bound to make a success of their clinical work. Unlike all of these groups, we were banned from publishing by the EMI management who wished to keep their work in NMR a commercial secret. This was in spite of the fact that they had issued a press release announcing the world's first NMR image of the head over two years before, in November 1978.⁵

There was also greater interest in spectroscopy than imaging at that time, and visitors to the UK would generally travel down the A40 to visit George Radda's NMR spectroscopy unit at Oxford without finding it necessary to stop and view the imaging at Hammersmith Hospital on the way. Brian Ross had already shown remarkable findings in McArdle's syndrome using their system.⁶

At about this time the magnet quenched and had to be warmed up. It was out of commission for five weeks. Although there were very few clinical results to show and our group seemed to be way behind the UK and international competition, there were some rays of hope. Gordon Higson and John Williams from the Department of Health seemed able to perceive some encouraging signs even if others could not. The physicists and engineers in the EMI group under the leadership of Ian Young had stuck to their task remarkably well and totally supported the clinical work. They would arrive within minutes of any machine breakdown and members of the group such as Alasdair Hall seemed more devoted and concerned with helping patients than the medical staff. Jackie Pennock was a versatile and remarkably able researcher and Professor Robert Steiner was an astute head of department. The patients also seemed prepared to put up with any amount of discomfort and inconvenience in the interests of research.

Forty-six volunteers and 48 patients had been examined prior to the magnet quench and there were insufficient data for any significant papers, but this period allowed a time for regrouping and establishing new targets for the three months prior to the Winston-Salem meeting on 1–3 October 1981. This was billed as a back-to-back showdown between the UK and US groups. The previous NMR meeting in 1980 at Nashville had not been a success because of lack of clinical results, but it was clear that a number of groups were now getting them and there was a pecking order to be established.

It was also becoming clear that while the T_1 -weighted inversion recovery was slow, it showed a remarkable level

of gray white matter contrast in the brain and there was often an amazing level of contrast between abnormal and normal soft tissue. Sometimes the contrast difference was so high it was difficult to display the images.

When the show down came at Winston-Salem it soon became apparent that other groups in the UK and US had had their difficulties too.⁷ In fact, Bill Oldendorf in his commentary on the meeting suggested that the poor showing of the US groups relative to those in the UK was due to excessive numbers of US physicists working in defense to the detriment of medical research.⁸ By this time we had sent off six papers⁹⁻¹⁴ and Picker International had bought the system from EMI.

At the Winston-Salem meeting it was clear that there was a considerable prize for whoever first performed the definitive NMR imaging study on the brain. The Massachusetts General Hospital group had the inside running with an operating system and great strengths in neurology and neurosurgery as well as the leading neuroradiologist in the world, Professor Juan Taveras. We thought this target worth pursuing and David Thomas (neurologist) and Christopher Pallis actively sought suitable patients while we made arrangements to study them at any hour of the day or night.

By the following January we had over 100 patients with conditions that included most of the common headings in neurology, but we then had a windfall. David Bailes had resurrected the spin echo sequence which previously had failed to show disease in its short echo time form and increased the echo time to 40, 80, and then 120 ms. This caused a wide range of lesions in the brain to shine out with high contrast (Figure 1). We had been fortunate enough to stumble on the most valuable screening sequence in NMR imaging—the heavily T_2 -weighted spin echo. Over a two-week period we recruited a further 30 patients and included these in two papers which were published in July¹⁵ and August 1982, the second of which described 140 cases.¹⁶ The largest published clinical series up until this time had been 10 cases.

By this stage we had begun studying infants and children and were able to show normal and delayed myelination¹⁷ as well as a wide range of disease.¹⁸ The logistics and practical problems in examining infants were overcome by Lilly Dubowitz, Linda De Vries, Frances Cowan, and Mary Rutherford. They proved remarkably patient with machine difficulties.

Although we had turned the corner in 1981 our reprieve was relatively short-lived. We lost ground in the second half of 1982 to other groups with multislice systems, including particularly that from San Francisco under Alex Margulis. In addition, most other groups were using two-dimensional Fourier transfer or the spin warp¹⁹ which was tolerant of motion and bad fields (rather than projection reconstruction which we were using). In the beginning of 1983, we changed to the spin warp system and, in response to a move from Technicare, to high resolution (256×256 matrix size). One of the secrets which made this possible was the use of tightly coupled coils in the form of helmets covering the head, collars around the neck, and corsets around the body.^{20,21} These low bandwidth techniques, Michael Burl's rf system, and David Gilderdale's display, enabled us to produce good quality high-contrast and high-resolution images on a routine basis using our low field (0.15 T) system (Figure 2).

Figure 1 Multiple sclerosis, February 1982: T_2 -weighted spin echo (SE1080/80) image of the brain. The lesions are highlighted (arrows)

Figure 2 Normal brain, March 1983: Sagittal IR1400/10/400 sequence. High contrast is seen between gray and white matter. The anatomical detail in the brainstem is well seen

We knew that the next Society of Magnetic Resonance in Medicine (SMRM) meeting in San Francisco in August 1983 would be a showdown between low-field and high-field systems. General Electric had launched their 1.5-T system and anticipated a very large increase in signal-to-noise ratio with it. If this proved to be the case, their system would completely

outclass all existing low-field and mid-field machines. On the opening day of the meeting, Ian Young produced a series of high-resolution images taken at 0.15 T and the expected demise of low field did not happen. In fact, the meeting became somewhat disorderly with hints that Ian Young was being less than honest about the time he was taking and the techniques he was using to acquire his remarkably good images. This same argument was replayed in the 1984 SMRM meeting in New York with more disorderly scenes and Ian Young almost stealing the show completely with a spectacular cervical spine image of syringomyelia. The gain in signal-to-noise with high field turned out to be much less than had been at first anticipated and could only be realized with a lot of hard work.²²

In the meantime David Bryant had successfully employed a phase sensitive technique for measuring flow.²³ He was later to implement 4D chemical shift imaging²⁴ as well as ¹³C spectroscopy on our 1.5-T spectroscopy system. Donald Longmore was later to transform this early flow work and made the dream of successful cardiac imaging a reality.

By the end of 1983, Schering had developed gadolinium-DTPA and begun volunteer studies with Roland Felix in Berlin. Ulrich Speck and Hans Pieter Niendorf were kind enough to provide us with this agent for clinical trials. While the first patient ever studied showed no change, the second was a spectacular success (Figure 3). Ten of the first 12 patients showed enhancement.²⁵

Walter Curati and Moshe Graif examined benign and malignant tumors with enhancement and performed detailed sequence comparison and time course studies.²⁶ The spinal cord studies were also a success.²⁷ With John Brown's help we obtained considerable mileage from this contrast agent before it was released more widely in the US and elsewhere in Europe.

After this, we again drifted behind the play, but made a special effort in 1985. Ian Young was the principal organizer for the SMRM Barbican meeting in London in 1985 and we wished to make an impression at this meeting since it was on our home territory. For this we implemented the field echo sequence with an echo time of 22 ms at 0.15 T to cancel red marrow and provide high contrast lesions of the bone marrow.²⁸ David Bailes and Alan Collins implemented respiratory ordered phase encoding to provide control of motion artifact in the abdomen.²⁹ The most spectacular images, however, were provided by the short inversion time inversion recovery (STIR) sequence with its fat suppression and very high lesion contrast.³⁰ It subsequently proved to be of considerable value in the musculoskeletal system, bone marrow, and the body as a whole, including oncology. Bruce Porter,³¹ Paul Goddard, Don Schnaff, and Alina Greco performed excellent studies with this technique.

The spectroscopy system which was designed and built by David Bryant and Alasdair Hall was installed in 1987. Clinical applications of the liver were initially developed by David Menon and refined by Simon Taylor-Robinson. These proved successful and the use of proton spectroscopy in birth asphyxia was developed by Carol Peden and taken further by Frances Cowan. Jane Cox provided the organizational framework and impetus for much of the work as well as for studies of scrapie in mice. Richard Iles provided help when it was acutely needed and Janet Sargentoni made an invaluable contribution on the clinical side. Jimmy Bell proved remarkably adept at in vitro

Figure 3 Brain metastases, December 1983: Inversion recovery (IR1400/5/400) sequence without (a) and with (b) intravenous gadolinium-DTPA. Ring enhancement is obvious in (b) (arrows)

animal and carbon studies, and provided the focus of much of the research work. Coil development for this system was taken on to a new plane by David Gilderdale, Reg Harman, and Michael Burl.

The development of the long echo time field echo provided high contrast imaging of cerebral hemorrhage at low field contrary to theoretical predictions based on 1.5 T work.^{32,33} This apparent miracle dealt with the issue of low-field systems being incapable of demonstrating the various phases of hemorrhage at the Montreal SMRM meeting in 1986.

Christine Baudouin undertook the development of internal coils and this was later taken over by Nandita deSouza.^{34,35} The images of the uterine cervix and ear were remarkable. Interventional studies starting with laser ablation of the prostate were begun under Nandita deSouza and Glyn Coutts's

Figure 4 Diffusion-weighted imaging in acute neonatal infarction, January 1994: T_2 -weighted spin echo (SE3000/120) (a) and diffusion-weighted image (SE pulse rate/200, through plane sensitization $b = 600 \text{ s mm}^{-2}$) (b). The lesion is poorly seen in (a) but is very obvious in (b) (arrows)

direction and with Rakesh Puni's help. This type of study may point the way to many future applications of MR imaging.

In 1992 Joseph Hajnal implemented another high contrast sequence, the fluid attenuated inversion recovery and it proved effective not only for lesions of the brain³⁶ and spinal cord³⁷ but also, under David Harris's direction, for detecting brain swelling in post-operative patients.³⁸ Diffusion weighted imaging developed by Joseph Hajnal and Angela Oatridge and applied by Frances Cowan, Jackie Pennock, and Jane Schwieso proved particularly suitable for the acute diagnosis of hypoxic ischemia injury in infants (Figure 4).^{39,40}

Joseph Hajnal's thorough analysis of the activation experiment set a new standard of image interpretation.⁴¹ At the present time the former EMI group and the Hammersmith clinical groups remain together. Nadeem Saeed and Joseph Hajnal have implemented a precise registration program which appears likely to have widespread application in detecting small changes in the size of the brain and other organs on serial examinations. Approaches to imaging the cortex including the doubly attenuated inversion recovery sequence and techniques for unfolding it are under way.

We benefited greatly from the excellent organization of Ann Case, Di Spencer, and Christine Soleimanpour who all subsequently ran their own units. We learned a lot about patient management and the conduct of clinical research from Eve Johnson and David Owens. We also learnt about efficient organization from Mary Ann Johnson, Susan Brothers Peterman, Beatrice De Coene, and Margarete Hayward.

We were greatly encouraged by Bill Bradley in Los Angeles and Peter Rinck in Europe who inspired us with their enthusiasm and took every chance to support our group. George Radda from Oxford also recognized the possibilities in imaging at an early stage and provided considerable help. Ian Isherwood from Manchester was another stalwart supporter over a long period. We also admired the Aberdeen group of John Mallard, Jim Hutchison, Meg Foster, Tom Redpath, and David Lurie, who achieved an enormous amount with a minute budget.

There were other lessons. We held on to our original prototype 0.15-T system for too long (1980–93). While it earned its place in the Science Museum (London), we should have changed to a commercial system much earlier. We became preoccupied by the high field–low field argument and stayed with our low-field system with its antiquated computer. As a result, we lost out on fast imaging, angiography, and close integration with Picker International systems.

From our earlier experiences we developed a fixation on the spectacular image which would transform the practice of MRI overnight. In 1981 and 1982, display of such an image at a conference would be greeted by 'oohs' and 'ahs' as well as a shower of camera clicks. We were able to achieve this with the T_2 -weighted spin echo, high-resolution images, contrast enhancement, STIRs, FLAIRs, diffusion-weighted, and other images, and these were of obvious diagnostic value. However, we pursued high contrast images of this type at the expense of other targets such as a reduction in imaging time and quantitative studies which might have been as, or more, productive.

We also operated from too narrow a funding base. While the Department of Health, Medical Research Council, and Picker International were all very helpful, we found the funding of new technological advances difficult and did not pursue other sources of funding with the necessary persistence.

The teaching was rudimentary and the balance between independent research and proper supervision always seemed wrong whatever way we played it. We also took a long time to come to understand and work with Picker International. In fact, it was not until Surya Mohapatra took control that the relationship with the company really improved.

For the first five years while we were the only clinical MR unit in London there was no problem in obtaining patient referrals from other hospitals in any clinical group, but once

other hospitals obtained their own systems this became more difficult and our clinical studies suffered.

At the end of 14 years of development two particular memories remain. One is of a large number of people completing patient examinations, papers, grant applications, machine developments, and other essential tasks against deadlines at all hours of the day and night. This included most people in the unit but particularly Patricia Hamilton and Dulcie Rodrigues. The other is of many people such as Jaume Gili, Iain MacKay, Giovanni Di Chiro, Max Andre Hopf, Steven McKinstry, Ros Dietrich, William Yuh, and Josef Assheuer who gave us their unstinting help.

Research interests: clinical applications of imaging and spectroscopy.

Callaghan, Paul T.: From γ -Rays to Gradients

Paul T. Callaghan

Massey University, Palmerston North, New Zealand

I am part of that generation which inherited nuclear magnetic resonance, having been born nearly two years after its discovery in 1945. I have no heroic tales to tell of the early days. I am simply one of those who followed after, who made a scientific life in this domain of the nuclear spin, and felt kindly treated by the experience. That experience is unremarkable except in one respect. Some explanation must be found for the persistence of nuclear magnetic resonance. It has survived for 50 years as an exciting field of research, not just because its applications are so vast in number, but because it is a subject which is scientifically rich and personally rewarding.

I began in magnetic resonance in a very odd way. As a graduate student in Oxford's Clarendon Laboratory I used to implant or diffuse radioactive nuclei into ferromagnetic host metals and then cool them down to milliKelvin temperatures using adiabatic demagnetization. The purpose was to measure nuclear hyperfine interactions. My thesis supervisor was Nick Stone, while my scientific 'grandparents' were Nicholas Kurti, Michael Grace, and Brebis Bleaney. Even then I was following the route laid down by others. My work involved using CW radio waves to detect magnetic resonance via disturbance to the nuclear γ -emissions as the spin sublevel populations were equalized. Hence I was able to measure the nuclear magnetic dipole moments of quite a number of unstable nuclei. During this time we learned of some remarkable anomalies in adiabatic passage experiments on ^{60}Co discovered by Geoff Wilson at Monash University in Australia. My fellow student, Peter Johnston, and I were lucky enough to discover the reason for this. It turned out that small quadrupole interactions in this high-spin nucleus caused successive pairwise inversion which, instead of reversing the spin magnetization, caused a cyclic permutation of populations. This led to dramatic effects in the γ -ray emission anisotropy and, ultimately, an unusual form of audio-modulated spectroscopy (MAPON) for measuring exceedingly delicate quadrupole splittings in the presence of overwhelming inhomogeneous line broadening.

The point of the story is simply this. I learned then the pleasure of thinking about spin gymnastics, and in enjoying what I call the 'instant gratification' experiment. The wonderful thing about nuclear magnetic resonance is that it allows exotic spin manipulations, in which one can test predictions against the immediate result, if not today, then at least within the month. That suits me perfectly.

My first contact with 'proper NMR' was a revelation. I was sent by Nick Stone to report our adiabatic passage results to the first specialized Colloquium AMPERE, held in Krakow in August 1973. I listened to Erwin Hahn, Raymond Andrew, Myer Bloom, John Waugh, and Alex Pines. I was simply astonished by the range and complexity of NMR *detected without γ -rays*. Peter Mansfield spoke on NMR diffraction in solids, one of his first reports of imaging, and a young woman graduate student from Robert Blinc's group, Metka Luzar, spoke about pulsed gradient spin echo (PGSE) NMR.

Although I didn't know it at the time, her talk was to be one of the most important influences in my scientific career. It was to be 20 years before I met Dr. Luzar again and could tell her this.

In 1974, I returned to my native New Zealand to take up a post as a physics lecturer at the newly formed Massey University. I wanted to get back to nuclear spins and one of my chemist colleagues, Ken Jolley, was kind enough to share his new 1.4 T NMR system with me. I decided to build a pulsed gradient spin echo diffusion attachment, aided by graduate student Craig Trotter. Remarkably, the apparatus worked so well that it opened up the possibility of studying a host of diffusion phenomena relating to molecular organization and semilocal motions in polymers, liquid crystals, emulsions, colloids, and just about every soft material considerate enough to contain protons with T_2 values longer than 1 ms. It turned out that we had solved, by sheer accident, some problems of instrumental artifacts which led to echo instabilities in PGSE NMR, and which had plagued attempts at using the method since its first demonstration by Stejskal and Tanner in 1965. I had stumbled on a productive 'niche' in magnetic resonance.

The use of magnetic field gradients led, inevitably, to imaging. Most of the emphasis in MRI had been on scaling apparatus up for whole body tomography and it was clear that by scaling down it was possible to take advantage of improved sensitivity and larger magnetic field gradients. This time I was helped by a remarkably talented graduate student, Craig Eccles, who built our first NMR microscope. The trick with NMR microscopy, whose resolution is really rather poor, is to find the right contrast. The amalgamation of PGSE NMR and imaging has led to a host of diffusion- and velocity-mapping applications, as diverse as the imaging of in vivo fluid transport in plants and rheometric studies of colloidal and polymeric fluids under shear. Imaging has also had a reciprocal impact on PGSE NMR where the application of Fourier diffraction approaches has provided us with some remarkable insight regarding restricted diffusion, in which the echo attenuation exhibits many of the properties of both elastic and inelastic scattering structure factors.

For all my fun with pulsed magnetic field gradients, my most concentrated lessons in NMR came from reading Abragam's book and by spending a year working in Myer Bloom's laboratory in Vancouver. Beyond those two individuals I could name a hundred more who have taught me so much. I learn best by listening to others speak or write with enthusiasm about their work. How fortunate I have been to work in a field in which so many wonderful scientists have participated. Charles Slichter told the 1993 Gordon Conference on magnetic resonance how writing his book gave him so much pleasure because he became, in the process, so familiar with the work of others. I share that feeling.

I believe that science is an intensely personal and creative activity which may be practised in many ways. Along with many of my nuclear magnetic resonance colleagues, I do my best work by dreaming up new tricks to play on the molecules via the nuclear spins, and then waiting with excitement for the result. To the younger scientist intent on joining NMR in its second half century I would say, find the approach which best suits your temperament and be alert for the role of chance and serendipity. There are more niches waiting to be discovered.

Research specialties: pulsed gradient spin echo NMR and NMR microscopy, molecular translational dynamics in porous media, in polymers and in other complex fluids.

Carr, Herman Y.: Early Years of Free Precession Revisited

Herman Y. Carr

Rutgers University, New Brunswick, NJ, USA

In early November 1949 the bulletin for the Chicago meeting of the American Physical Society arrived in Cambridge at an opportune time for me. It was the beginning of my second year as a Harvard graduate student, and with the guidance of Edward Purcell I had just begun to read about nuclear magnetic resonance. That bulletin contained the abstract¹ of Erwin Hahn's contributed paper to the Thanksgiving meeting—the historic announcement of the phenomenon of 'spin echoes'! Purcell suggested that I read the abstract and try to understand this fascinating effect. Thus began an exciting three-year period for me as one of Purcell's graduate students in a new and rapidly developing area of physics.

Many of the results which developed from that research were published in two papers. The first paper² reported the observation of an indirect electron-coupled nuclear spin–spin interaction in HD gas. Purcell and Norman Ramsey³ had predicted the existence of such an interaction as they successfully sought to explain the recently discovered high-resolution and field-independent J coupling.

The second paper⁴ emphasized many of the experimental procedures which evolved from our research both at Harvard and during my first two years at Rutgers. These technologies included the use of 90° and 180° pulses in free precession experiments, a method for measuring the transverse spin–spin relaxation time T_2 even in the presence of diffusion through the magnet inhomogeneity, the inversion recovery method for measuring the longitudinal spin–lattice relaxation time T_1 , and the intentional application of field gradients to study spatial effects (diffusion and flow).

In the following commentary I focus not so much on the technical description of the results already reported in the above two papers, but more on several episodes related to the birth of ideas preceding the results. Most of these episodes were reported in my 1952 Harvard thesis.⁵ The thesis provided more opportunity for describing the unfolding of new ideas than did the shorter papers.

ECHOES IN THE NIGHT AND AT LUNCH

In his experiments at the University of Illinois, Hahn⁶ used two equal rf pulses to induce his spin echoes. These echoes were not easy to understand. Hahn explained them using a model involving only equatorial components of precessing nuclear moments. But Purcell suggested using a three-dimensional model, and although this greatly simplified the understanding, the explanation of the various echoes

induced by two equal pulses still was quite challenging. Indeed, in a letter to Hahn on December 14, 1949, Purcell wrote 'I see how the dimple-sphere comes about; last night while lying awake I was able, in a particularly lucid moment, to flop the cones around mentally and trace what happens ...'

During the Christmas recess while attending a student conference at Urbana, I left the political activity of the conference one afternoon and visited Erwin Hahn in his cramped laboratory at the top of a high stairwell. It was exciting for me to see spin echoes for the first time and to hear details of their discovery. In the spring term Purcell and I decided to pursue our interest in free precession techniques and to plan for the necessary apparatus. Like Hahn who had worked with pulse apparatus in the Navy during World War II, I had worked with pulse apparatus in the Air Force. This was a great help. Our Harvard apparatus, however, differed from that in Illinois in a special way—we incorporated several independently variable pulse gates for an important reason.

It was during lunch one day, while explaining spin echoes to another graduate student, that I realized the explanation could be further simplified by considering two unequal pulses—a 90° pulse followed by a 180° pulse. Moreover it was easy to understand how a sequence of echoes could be induced by following one initial 90° pulse with a sequence of 180° pulses. Later that afternoon after a departmental seminar I told Purcell about this idea. I still recall and appreciate his delighted response, 'Elegant!' A similar response which I have long remembered came from Ramsey about two years later near the conclusion of my graduate work. After weeks spent searching for the predicted J coupling in the HD molecule—including many nights of discouragement—I finally found the predicted modulation of the free induction decay following a 90° pulse, first for the proton signal and then for the deuteron signal. Ramsey was away from Cambridge for that part of the summer recess. When I telephoned him with the news, his delighted response was, 'Best news all summer!' It was good to experience so vividly the fact that discouragement does not last forever!

These memories also remind me how important it is for faculty members to share their delight and enthusiasm with students and other colleagues.

SAMPLE SPINNING AND A NEW TYPE OF ECHO

The spinning of samples to reduce the effect of magnetic field inhomogeneity in high-resolution experiments had its origin in the development of a new kind of spin echo. The idea for rotating the sample came from an analogy with the sequence of 180° rf pulses and echoes described above. These spin echoes could be explained as in Figure 1 by the way a 180° rf pulse tips the equatorial plane of incremental magnetic moments associated with the various parts of a sample located in an inhomogeneous field. After each 180° tip the previously dispersing moments start to recluster and eventually form an echo after a time spent reclustering that is exactly equal to the time spent dispersing before the 180° tip.

There is another way, however, to obtain such reclustering without resorting to the forced nutation from a 180° pulse at the resonance frequency. This was particularly easy to predict

Figure 1 The formation of an echo (from Ref. 4). Initially the net magnetic moment vector is in its equilibrium position (a) parallel to the direction of the strong external field. The rf field H_1 is then applied. As viewed from the rotating frame of reference the net magnetic moment appears (b) to rotate quickly about H_1 . At the end of a 90° pulse the net magnetic moment is in the equatorial plane (c). During the relatively long period of time following the removal of H_1 , the incremental moment vectors begin to fan out slowly (d). This is caused by the variations in H_z over the sample. At time $t = \tau$, the rf field H_1 is again applied. Again the moments (e) begin to rotate quickly about the direction of H_1 . This time H_1 is applied just long enough to satisfy the 180° pulse condition. This implies that at the end of the pulse all the incremental vectors are again in the equatorial plane. In the relatively long period of time following the removal of the rf field, the incremental vectors begin to recluster slowly (f). Because of the inverted relative positions following the 180° pulse and because each incremental vector continues to precess with its former frequency, the incremental vectors will be perfectly reclustered (g) at $t = 2\tau$. Thus maximum signal is induced in the pickup coil at $t = 2\tau$. This maximum signal, or echo, then begins to decay as the incremental vectors again fan out (h)

if the inhomogeneity of the static field comes from a uniform gradient in one direction across the sample. Sometime shortly after an initial 90° rf pulse, one simply rotates the sample 180° about an axis along the length of the cylindrical sample, so that each nucleus that previously experienced a field larger than the axial field by a certain amount now experiences a field that is smaller than the axial field by the same amount. Just as for the previous echoes which were induced by 180° rf pulses, the incremental magnetic moments which were previously dispersing begin to recluster. And after the time spent reclustering is equal to the time spent dispersing, all the incremental moments will coincide with the incremental moment associated with the axial field. The sample rotation has produced an echo! The phase of this echo, however, is the same as the phase of the free induction decay (FID) following the original 90° rf pulse. This is in contrast to an rf-induced echo which would be 180° out of phase with the FID, assuming that the rf phase of the 180° pulse is the same as for the 90° pulse.

This new type of echo, no longer induced by the forced nutation associated with an rf pulse at the resonance frequency, was subsequently obtained by others by simply reversing the sign of the static field gradient.⁷ At the time the echo is formed the incremental moments previously dispersing in too large (or small) a static field will have spent exactly the same

time reclustering in too small (or large) a static field. Persons working with such echoes in today's imaging experiments often call them 'gradient' echoes in contrast to the previous 'spin' echoes. But this is a misnomer—all these echoes are 'spin' echoes associated initially with dispersion and then reclustering from a 'gradient'. The significant difference is that the original type of spin echo is induced by the forced nutation from rf pulses at the resonance frequency. Thus, changes in the populations of the Zeeman energy levels occur. For the new type of echo with no rf pulses at the resonance frequency, there are no such changes. A sequence of the resonance-induced echoes can experience forced saturation. In contrast, a sequence of the new nonresonance-induced echoes is only associated with relaxation, but not forced saturation. This is a crucial distinction in applications such as fast imaging.

The new type of echo can be induced by changing the sign of the gradient either abruptly or steadily, and similarly by rotating the sample either abruptly or steadily. In the original 1951 Harvard experiments the sample was rotated steadily on the end of the long wooden shaft from the motor shown in Figure 2. The motor was located outside the magnet gap so that no metal parts moved in the strong magnetic field. The

Figure 2 Motor used to induce nonresonance mechanical echoes. From Ref. 5

Figure 3 A sequence of nonresonance-induced echoes using motor in Figure 2. From Ref. 5

observed echoes shown in Figure 3 altered their spacing as a function of motor speed exactly as predicted.

It was this sequence of nonresonance-induced echoes that enabled us to see the previously discovered fine structure or chemical shift in ethyl alcohol.⁸ Our Harvard magnet was too inhomogeneous to reveal fine structure easily. We saw no chemical shift modulation on the FID following a single 90° rf pulse—the rapid dispersion of the incremental moments associated with the inhomogeneity of the magnet came much faster than the slow dispersion from the relatively

small inhomogeneity associated with the nonequivalent nuclear locations in the ethyl alcohol molecules. Nor did the original type of resonance-induced echoes produce evidence of the chemical shift—these pulses reclustered the dispersion from both the external inhomogeneity of the magnet and from the internal inhomogeneity of the different locations in the molecules. However, for the new type of echoes, the reclustering was associated only with the external magnet not with the different locations within a molecule. Thus the modulation of the envelope of our new type of echoes as in Figure 4 revealed the existence of the chemical shift. This proved to be very important for high-resolution spectroscopy. By increasing the rotational speed of the motor, we were able to observe this modulation without the typical echo effect. The individual echoes simply merged together. This FID—actually, a merger of echoes—following the initial 90° rf pulse was equivalent to the FID obtained from the same sample at rest in a much more homogeneous field. The sample spinning procedure is now commonly used in high-resolution spectrometers to reduce the effect of magnet inhomogeneity.⁹

Not all of our samples were candidates for such spinning. For precarious high-pressure gas samples sealed in glass tubes—for example, the HD samples—we used electric currents in the shim coils shown in Figure 5 to reduce the inhomogeneity, a technique also now commonly used in high-resolution spectrometers.¹⁰

IMAGING AND ‘MENTAL’ FOURIER TRANSFORMS

The Fourier transform relating (a) the time dependence of the FID following a pulse and (b) the frequency or field

distribution of the molecules was recognized very early in our work. Initially this relationship was used to determine the lineshapes in our relatively inhomogeneous magnet. More interesting applications came after we began to improve magnet homogeneity by both sample spinning and the use of electric shims. These improvements made it possible to use our magnet to observe as in Figure 4 and Figure 5 more complicated FIDs caused by chemical shifts and indirect spin–spin couplings.

Some may think that fast Fourier transforms (FFTs) were not a part of free precession work until after the development of fast computers or ‘electronic brains’. Not so! Very early we used our own brains to make speedy Fourier transforms of at least the simpler FIDs we were observing. The simplest FID—for example, the deuteron signal from our HD gas—consisted of a pure sinusoidal beat signal which we immediately recognized to be the Fourier transform of a distribution consisting of two lines of equal intensity. This was precisely the Ramsey–Purcell prediction³ for an indirect spin coupling between H and D. Essentially half of the deuterons have proton neighbors with nuclear spin up, while the remaining half have proton neighbors with spin down.

Slightly more complicated was the modulation observed on the proton FID from acetic acid, CH_3COOH . Here the minima between the peaks of the modulated envelope of the beat signal in the FID did not go to zero, but only down to half the intensity observed at the peaks. Even without knowing the chemical structure for acetic acid, we could mentally transform this FID to a field distribution consisting of two lines—but now with one line having an intensity three-times larger than the other. The magnitude ratio for the peak intensities of the beat modulation becomes $(3 - 1)/(3 + 1) = \frac{1}{2}$ instead of the $(1 - 1)/(1 + 1) = 0$ ratio for the above deuteron signal from HD gas. The different field values for acetic acid correspond to different diamagnetic shielding at the nonequivalent locations of the protons—the first field at the locations of the three equivalent protons in the CH_3 group and the second field at the location of the one proton in the COOH group. The sensitivity of the above FIDs to changes of the external field value helped identify the type of shift—the indirect nuclear spin coupling was field independent while the chemical shift was field dependent.

The ‘mental’ Fourier transforms were not too difficult even when three spin groups were involved, especially when—as for the proton resonance in HD gas where the neighboring deuterons had spin 1—the three lines had *equal* intensity. But when the intensities of the three lines were *unequal*, and when the number of lines increased, the ‘mental’ Fourier transforms became quite difficult. Fortunately for NMR spectroscopy, and for MRI, the development of fast computers came to the rescue! Richard Garwin who had experience studying helium using NMR free precession techniques at IBM provided the crucial stimulation for Tukey and Cooley to develop their fast Fourier transform (FFT), published in 1965.¹¹ This stimulation did not originate in a study of line structure—simple helium lines have no fine structure. It arose from the coincidence of Garwin’s time-consuming calculations concerning the alignment of nuclear spins in solid helium and his participation in a 1959 meeting concerned with the detection of underground nuclear explosions! This unique coincidence set the stage for Garwin’s encounter with Tukey and Cooley.¹² Both NMR

Figure 6 Comparison of FIDs from ethyl alcohol phantom (synthetic) and from a sample of real ethyl alcohol (natural). H_3 , H_2 , and H_1 are signals from the small rubber samples cut in the volume ratios 3:2:1. From Ref. 5

and MRI—and, indeed, nearly all fields of science—have benefited enormously from this coincidental encounter!

Our increasing difficulty with ‘mental’ Fourier transforms as the NMR line structure became somewhat more complicated, and the total absence of FFTs in 1951, led me to a one-dimensional imaging experiment. Visitors to our laboratory had little trouble understanding the above relatively simple FIDs from the protons in HD or CH_3COOH . But the much-discussed FID from ethyl alcohol, CH_3CH_2OH , gave a lot of trouble. The recently discovered chemical shift in ethyl alcohol involved three proton lines with intensities in the ratio 3:2:1. About this time we were intentionally superimposing a uniform gradient onto the main homogeneous magnetic field in connection with our diffusion studies. The gradient provided information on spatial location—each position corresponded to a different resonance frequency. Therefore, in order to help visitors understand the origin of the rather strange ethyl alcohol FID in Figure 5(c), I constructed a phantom—in the 1952 thesis I called it ‘synthetic alcohol’. The phantom consisted of an rf coil stretched out along the uniform gradient of the static field. Three small pieces of rubber which had a strong proton resonance were placed in the coil at positions such that the ratio of the differences of the separations of the pieces, and therefore the ratio of the differences of their resonance frequencies, was approximately the same as for the ratio of frequency differences associated with the three lines of the real ethyl alcohol resonance. Moreover the volumes of the three small pieces of rubber were cut in the ratios 3:2:1 to correspond to the alcohol line intensities. To observe the FID in the time domain, we simply applied a 90° rf pulse. As expected, the phantom FID shown in Figure 6(a) looked very much like the real alcohol FID in Figure 6(b). This experiment had two results. Implicitly, it demonstrated crucial steps of the imaging concept: the use of the *Fourier transform* to relate the signal intensity in the time domain to the signal intensity distribution in the frequency and field domain, and the use of the *uniform gradient* to relate the signal intensity distribution

in the frequency and field domains to the inhomogeneous spin distribution of the sample in the spatial domain. Explicitly, however, it enabled the visitors to ‘look’ at the phantom in the magnet and at the FID on the oscilloscope screen, and thus convince themselves that this relatively complicated FID does indeed come from this spatially inhomogeneous sample—three small *separate* pieces of uniform rubber with nuclei numbers in the ratio 3:2:1.

A word of caution comes from this phantom demonstration. When only the macroscopic external uniform gradient and the macroscopic structure of the phantom produce the signal intensity distribution in the frequency or field domain, the FID can be used to deduce the macroscopic structure of the phantom. But for the real ethyl alcohol sample in a homogeneous external field, the chemical structure of the signal intensity distribution in the frequency and field domains originates from the internal inhomogeneity within each molecule. Therefore the Fourier transform of the alcohol FID reveals the chemical shift, not macroscopic spatial structure. The simultaneous presence of a detectable chemical shift and an external gradient may complicate the spatial imaging. This complication has been exploited to improve some modern medical images.

FLOW AND MYSTERIOUS EVEN-NUMBERED ECHOES

A discussion of the effects of coherent molecular motion—convection and flow—was included in our 1954 paper. The even echo rephasing—or more precisely the odd echo dephasing—was used to establish that convection was not present when we used the new NMR technique to measure the diffusion coefficient of water.

The experimental results for diffusion and flow reported in the 1954 paper were obtained at Rutgers in 1953 using Henry Torrey’s excellent new electromagnet shown in Figure 7. To the best of my knowledge, it was the first magnet commercially designed and built for NMR work. At Rutgers the intentionally superimposed uniform gradient came from two coaxial current loops shown in Figure 8 with current flowing in opposite directions. The gradient is uniform over the largest volume when the square of the diameter of each circular loop is equal to $\frac{4}{3}$ -times the square of the loop separation. I called them ‘anti-Helmholtz’ coils. Later I learned that James Clerk Maxwell, while writing about a three-coil galvanometer,¹³ considered two such loops. They have been called a *Maxwell gradient pair*, the next most elementary circular current configuration following *Ampere’s loop* and a *Helmholtz field pair*.¹⁴ The sample at Rutgers was water flowing steadily through a plastic tube that threaded the rf coil.

My first encounter with a flow effect, however, occurred at Harvard in 1951 under vastly different conditions. Initially I observed relaxation times for fluid samples. At one point, however, we thought it would be interesting to look at the relaxation in a solid sample. So I froze one of my ethane samples by immersing it in liquid nitrogen and then moved it quickly into the rf coil. Thus I had a brief opportunity to observe the echoes before, while, and just after the sample

Figure 7 The 1947 electromagnet built by General Electric for Rutgers, specifically designed for magnetic resonance use: 0–1.5 T magnetic field, 18.0 in. diameter pole faces, 3.5 in. gap width with variations less than ± 0.001 in. The yoke consisted of two major pieces, each weighing 4500 lb; the two coils each contained 700 lb of copper

melted. Obviously there were huge temperature gradients present. What I observed is described in some detail in the 1952 thesis. One effect in particular was mysterious and almost unbelievable. The second echo shown in Figure 9 was larger than the first! How could the echo midway between the second and third 180° pulses be more intense than an earlier echo between the first and second 180° pulses? This was contrary to all our usual experience and understanding of echo formation!

After some days of puzzlement we became more aware that in our previous thinking about echoes we almost always made certain implicit assumptions. One was that each molecule in the inhomogeneous magnet experienced exactly the same static field while dispersing before the 180° pulse as it experienced while reclustered after the pulse.

Clearly we had to modify our analysis to account for convection and for steady flow. The new analysis was reported in both the 1952 thesis⁵ and the 1954 paper.⁴ The even-echo rephasing shown in Figure 10 was finally well understood. Moreover, an improved understanding of the effect of diffusion evolved from these new insights into the effect of coherent flow. Although Hahn and Charles Slichter had correctly analyzed the effect of diffusion on the FID following the initial rf pulse, the expression in Hahn's 1950 paper⁶ did

Figure 8 Maxwell gradient pair for obtaining uniform gradient: 2.0-in. diameter coils with separation distance adjustable from approximately 1.0 in. to 2.0 in. (to fit easily into the 3.5 in.-gap of the magnet in Figure 7). Knurled nut at bottom center was used for experimental adjustment of ideal diameter to separation ratio to correct for finite thickness of wire and number of turns in each coil. Constructed by master machinist Ralph V. H. Campbell of Rutgers Physics Machine Shop

not fully account for the effect of diffusion when a second rf pulse induced an echo. In particular, Hahn's analysis did not account for the ability of the Carr–Purcell pulse sequence to circumvent the effect of diffusion on echoes when more 180° pulses were interspersed between the 90° pulse and the final echo. Assuming a random walk model for diffusion through the inhomogeneous field, Purcell used two examples to consider a final echo intensity after eight random walk steps in the uniform gradient of an inhomogeneous field. In the first example an echo after the eighth step came in response to a single 180° pulse after the fourth step. In the second example an echo also came after the eighth step, but now in response to two 180° pulses—the first 180° pulse after the second step and the second 180° pulse after the sixth step. Another echo, of course, appeared after the fourth step. As he suspected, Purcell's tabulations for the phase distribution function of

Figure 10 Even echo rephasing in flowing water. Rutgers, 1953. From Ref. 4

the first example with only *one* 180° pulse revealed a less intense echo after the eighth step than did the tabulations for the second example with *two* 180° pulses. Clearly the 180° pulses had the ability to eliminate part of the decay caused by diffusion!

Using Purcell's eight-step analysis as an incentive, and with the help of a lunchtime discussion with fellow graduate student Richard Milburn, I extended the analysis to an arbitrarily large number of steps, interspersed with an arbitrary number of 180° pulses. The result confirmed the Hahn–Slichter analysis for the behavior of the FID following a 90° pulse, and at the same time fully accounted for all our new experimental observations for the echoes.⁴ Several years later in a very beautiful paper¹⁵ Henry Torrey, by modifying the Bloch equations to include diffusion terms, confirmed the results of our random walk analysis.⁴

That fleeting glimpse of what appeared at first to be a mysterious even-numbered echo opened the door to applications beyond all our expectations. The new understanding of the effect of coherent motion on the phase of the NMR signal eventually pointed the way to the development of phase contrast magnetic resonance angiography (MRA) now commonly used in clinical work.

EPILOGUE

Space does not permit me to comment on more of the events during those three years at Harvard and the many additional benefits I received from the insight of other graduate students and faculty, especially Fred Reif, George Benedek, and Robert Pound. Nor is there space to describe in any detail the enjoyable and exciting times, despite some faulty starts and discouraging moments, I have had in subsequent years at Rutgers. Again I have benefited from many wonderful colleagues—students, postdoctoral fellows, faculty, and staff.

During the past 40 years, NMR in our laboratory has been less a field of study in itself and more an experimental technology that enriches other fields of study. To be sure, occasionally new techniques were added to those developed in the earlier years at Harvard. I find it fascinating that some of these Rutgers techniques—for example, nondestructive measuring¹⁶ (now known as driven equilibrium) and steady-state free precession¹⁷ were in large measure devised to help

graduate students complete in a reasonable amount of time the measurements needed for their dissertations. The time needed to study slow-relaxing dilute xenon gas was undoubtedly the greatest challenge—the time needed for those measurements had to be reduced from years to months! Today these same techniques, along with the multiecho Carr–Purcell sequence (both resonance- or non-resonance-induced echoes), contribute to the development of fast imaging in medical applications. But now the time change is from hours to minutes or even seconds!

The central focus of my research at Rutgers, however, has been a study of fluids—a challenging state that lacks both the dilute gas simplification of extreme randomness and the solid state simplification of immense order.

An important part of our early research in fluids was the discovery made with Ralph Streever of a strong density-dependent local magnetic field shift in xenon.¹⁶ Although some do, I prefer not to call this a chemical shift—its origin is *intermolecular* not *intramolecular*.

This shift played a crucial role when later our studies extended to the liquid–vapor critical region—a rich meeting place for experiment and theory. We used the local field shift to measure density. Perhaps our most important contribution to the renaissance of critical point studies was the experimental determination¹⁸ with Larry Stacey and Barry Pass that, even in the absence of gravitational complications, the shape of the liquid–vapor coexistence curve accessible to experiment near the critical point clearly could not be described by a pure-power law with a single critical exponent. Later, a temperature quenching technique¹⁹ was developed in our laboratory. This enabled us to work even closer to the critical point despite the complications always associated with gravitationally induced density gradients. Using this technique, Cecil Hayes and I made an NMR determination of the leading correction term to the power law describing the liquid–vapor coexistence curve.¹⁹ The result was in agreement with the renormalization group prediction.

Our current research includes MRI studies of temperature quenching near the liquid–vapor critical point. NMR free precession between the forced nutation during pulses still continues to be an essential part of our explorations. It has been and continues to be a lot of fun! And the applications—beyond all our expectations—are deeply gratifying. It seems that almost each month brings new excitement from the excellent NMR and MRI work currently being done by what surely must by now be many thousands of innovative biologists, chemists, engineers, physicians, physicists, and others.

Clough, Stanley: NMR and Quantum Tunneling Rotation

Stanley Clough

University of Nottingham, Nottingham, UK

When the first NMR observations of the quantum tunneling rotation of hindered methyl groups were made in 1952 it could not have been anticipated that they would lead to a scientific puzzle involving a fundamental aspect of quantum theory, only unraveled 40 years later. Already in 1952, motional narrowing and spin–lattice relaxation of rotating methyl groups were nicely explained by the classical model of random hopping rotation. When the NMR line of some methyl-containing materials failed to broaden at low temperatures it was correctly attributed to quantum tunneling, the stationary states of the group being orientationally delocalized. Since the same samples obeyed the orientationally localized hopping model at high temperatures, it was natural to envisage a continuous evolution from the delocalized stationary states to the localized hopping states such as occurs in the band-to-hopping transition in linear transport. Early attempts to construct a continuous theory looked promising but soon came up against an impasse. The quantum theory of molecular rotors was incompatible with the hopping theory.

My involvement in tunneling spectroscopy began in 1966 with EPR studies of free radicals containing methyl groups. With the advantage of resolved hyperfine structure and different spectra at low and high temperature, we were able to study details of the continuous evolution between tunneling and hopping. The results disagreed radically with expectations based on the theory of spin symmetry species, suggesting where the solution to the theoretical problem would ultimately be found. ENDOR brought the first measurement of a tunneling frequency. Weak tunneling sidebands of EPR and NMR spectra were predicted and found by single and double resonance techniques. Experiments detecting internal resonances between tunneling frequencies and the electron Larmor frequency of paramagnetic impurities introduced level crossing methods to tunneling spectroscopy and field cycling techniques. Similar resonances were soon discovered with nuclear Larmor frequencies. High-field NMR studies of tunneling were hampered because of weak transitions. Low-field NMR though turned out to be unexpectedly powerful, as did tunneling spectroscopy in the rotating frame. The techniques to which many people contributed opened a succession of frequency windows on tunneling spectroscopy from a few kHz to tens of GHz. As the spectroscopy became routine, our thoughts turned during the 1980s to the next phase. With the development of NMR as a model, it was natural to consider the time domain and the evolution of superpositions of methyl tunneling states. Having the form of rotating wavepackets, these are a coherent version of the hopping rotation, and they similarly modulate the dipole–dipole interaction with interconversion of rotational and spin angular momentum and energy. When the conversion is described by incoherent transitions, nuclear

spin thermodynamics are extended to include molecular rotation with a rotational reservoir and temperature. When treated coherently, rotational and spin dynamics are unified. Throughout this period the theory remained broken-backed. There was one theory for low temperature data and one for high temperatures.

The theoretical puzzle concerns the labels used to identify fermions in quantum mechanics. In classical mechanics identical particles are identified by their trajectories. A particle may only be referred to as ‘the particle in trajectory j ’, not as ‘particle j ’. These are respectively trajectory and particle labels. Superficially they may appear the same, the distinction between them being quite subtle. The conversion of $a(i)b(j)$ to $a(j)b(i)$, where a and b are trajectories, occurs with the exchange of particles if i and j are particle labels and with the exchange of the meanings of the i and j if they are trajectory labels. Quantum mechanics borrows terms for the interactions of identical particles from classical mechanics and these are naturally expressed using trajectory labels. Quantum mechanical statefunctions, however, are written in terms of the illegal particle labels, compensated by imposing a constraint on the statefunction requiring it to be antisymmetric with respect to exchange of the labels. The inconsistent use of labels and the dynamical constraint are the source of many problems of which the reconciliation of quantum and classical theories of methyl rotation is only one. The general problem is resolved by formulating quantum mechanics using only trajectory labels. Then antisymmetrization of a trial statefunction only involves meaning exchanges. By revealing when two or more of the fermion trajectories are identical, a condition forbidden by the exclusion principle, it enables allowed eigenstates to be selected. With this role it imposes no dynamical constraint and is compatible with classical mechanics. With the excitation of wavepacket states the trajectory labels introduce the rotation and other coordinates which feature in classical theories and provide a description of particle dynamics which parallels the spin dynamics of NMR.

The removal of the constraint also makes the theory of quantum rotation transformable between rotating reference frames. This ensures that the relativity principle is satisfied and is also an important step in the unification of rotation with spin dynamics in which the use of rotating frames plays a vital role. A single theory can be devised encompassing both the high-temperature hopping model and the low-temperature tunneling states, while at low temperatures rotational wavepackets evolve coherently under the influence of the dipole–dipole interaction in a unified rotation and spin dynamics. All of the concepts of NMR can be extended to this wider field. Since rotational relaxation times are very long at low temperatures, time domain experiments can be envisaged in which spin order and rotational order are interchanged, opening a new field of coherent lattice dynamics for ingenious experimentalists. The intimate relationship of NMR and quantum tunneling rotation has been long obscured by conceptual problems. With these out of the way the future could be richer than the past.

Codrington, Robert S.: Comments on NMR Instrument Development

Robert S. Codrington

Los Altos Hills, CA, USA

When my thesis work started at Notre Dame in the fall of 1948 it was intended that I would investigate phase changes in polymers by high-frequency dielectric measurements. Before work actually started however, Felix Bloch stopped at the university to visit his friend and my thesis adviser Gene Guth. Bloch questioned us about why we weren't using NMR in the study of phase transitions rather than dielectric constant, since the polar groups in polymers were usually associated with the backbone or more rigid sections of the polymer molecules whereas the phase transitions were often governed by the motion of the end or terminal side groups of the molecule. He suggested that we talk to Herb Gutowsky and Herman Marks about it and shortly thereafter my thesis subject was changed to NMR in polymers. Earlier training as a radar specialist had provided me with an ideal background for designing NMR instrumentation, and it was not just a coincidence that all the inventors of NMR had played an important role in radar development.

In 1951 I joined the Physics Department at Rutgers University working for Henry Torrey on a project for the Office of Naval Research to investigate the use of magnetic resonance in submarine detection. Torrey had published his paper on the transient solutions of the Bloch equations using the Laplace transform methods and my work with him proved to be very useful for later work with Fourier transform systems. By the fall of 1952 I was sharing an office with Herman Carr who had come to Rutgers to complete his thesis and use their large homogeneous magnet for some of the new spin echo experiments which he and Purcell wished to carry out. Discussions with Carr as well as my involvement in testing the Navy's magnetometers, including the Russell Varian/Martin Packard free induction system, gave me a good introduction to transient NMR instrumentation.

The Schlumberger Corporation wished to apply the submarine magnetic resonance techniques to the detection of oil in geological formations and in 1954 I was hired to work with their consultant Nicolaas Bloembergen in trying to improve the sensitivity of NMR detection for this application. We designed a number of CW and pulsed NMR systems, one of which became a commercial instrument, and although the oil well instruments were never completely successful they did anticipate future developments in NMR imaging. In the period 1957–62 I became associated with the Navy missile programs and had access to the new digital systems which later had application to NMR designs. The Schlumberger NMR products were sold to Varian in 1961 and I joined the company in 1962.

My first job at Varian was getting the new A-60 spectrometer into production. It was an external lock system with a calibrated chart display for high-resolution spectra and became widely used for routine organic chemical analysis. The advantages of the lock and calibrated charts were so helpful to the

chemists that the older research spectrometers were upgraded to include them. A time-averaging computer, which digitized and stored the CW data, was also added to the product line. By the late 1960s work in the Varian laboratories by Wes Anderson and Richard Ernst in time-averaging time domain (FID) data, by Harry Weaver in using a higher field supercon magnet, by Ray Freeman in obtaining very high resolution performance, and by Jim Shoolery in developing tools for molecular conformation studies made it evident that a new type of research NMR spectrometer would be needed in the 1970s. Unfortunately, the costs of the different components needed for such a spectrometer were at that time just too expensive for use in a commercial instrument, and manufacturers compromised by selling hybrid CW/Fourier transform systems such as the Varian XL-100.

By the early 1970s rapid changes were occurring in the electronic and computer industries, all of which would have an impact on the design of NMR spectrometers. The improved noise figure of transistors resulted in much better receivers and higher frequency components made it possible to mix at gigahertz frequencies in synthesizers used to generate the three basic NMR frequencies (observe, lock, and decouple), thus avoiding the harmonic mixing ghosts that had plagued earlier synthesizers. Lower cost computers became available which used RAM memory in combination with fast i/o hard disk storage rather than magnetic core memory. Faster ADCs with larger dynamic range and low cost microprocessors also became available. The quality and stability of superconducting wire improved significantly and new designs of the magnet Dewar systems increased the liquid helium hold time by more than 10 times. Additionally, the use of new structured programming languages such as Pascal and C increased the speed and efficiency of developing large software packages needed for multidimensional NMR and new pulse sequences. Varian was able to utilize all this new technology in the XL-200 spectrometer (1978), and by 1980 all commercial research NMR spectrometers were incorporating most of it in their designs.

In the mid-1970s, Ernst and Packard as well as Derek Shaw and Felix Wehrli in Europe had encouraged Howard Hill and myself to keep up with developments in the MR imaging field. In 1983 we began the development of a series of spectrometers combining both NMR spectroscopy and NMR imaging in fields up to 7 T for use with smaller animals. By 1991 the latest system in this series, a whole body (1-m bore) 4 T unit developed in cooperation with Siemens, was completed. Recent results on this system and the new very high field spectrometers have demonstrated that if a breakthrough could be made in high-temperature superconductors it would open up new horizons in NMR applications.

Cohen, Jack S.: Recollections of Early NMR Applications to Proteins and Cells

Jack S. Cohen

Georgetown University Medical Center, Washington DC, USA

In 1966 I arrived in the US for the first time, as a postdoctoral fellow at Oleg Jardetzky's laboratory at Harvard Medical School in Boston. Until then I had mainly done nucleotide chemistry and ^{31}P NMR,¹ but I had decided that I wanted to learn more about proteins, specifically using NMR methods.

When I arrived, I met John Markley and Donella (Dee) Meadows, who were both just finishing their graduate work in the lab on NMR of polypeptides. A paper had recently appeared² from the laboratory of Harold Scheraga at Cornell, in which three pH-dependent signals were reported in the downfield region of the proton spectrum of Ribonuclease A at 60 MHz. The spectra were terribly noisy, however, and the analysis seemed confused, since RNase has four histidine (His) residues. Dee Meadows, who had a wonderful touch with the old Varian HR-60 machine in the basement of the Medical School, ran some spectra of Ribonuclease A at very slow scan rates and managed to see four resonances at certain pH values.

Very soon after I arrived, Oleg had decided to move to Merck Research Labs in New Jersey, where they had a Varian HA-100 that was equipped with an analog computer of average transients (CAT) to improve signal-to-noise. We immediately began running the spectra of several proteins to look for their histidine imidazole signals. Initially Dee studied RNase, John chose staphylococcal nuclease, and I focused on lysozyme.

Lysozyme was a much studied protein because it is readily available (from hen egg whites) and is extremely stable. One other point that particularly attracted me was that it had only one histidine residue, at position-15 in the amino acid sequence. Since the origin of the signals seen in the RNase spectrum was controversial, I thought that if I could see one titrating resonance, that would clarify the issue.

In fact I did see one titrating resonance, and was able to assign this to the imidazole ring C-2 (or C- ϵ) proton of His-15. Thus, this was the first individually resolved proton in a protein NMR spectrum that was unequivocally assigned. This, as well as the observation of four titrating resonances at some pH values in RNase and *Staph.* nuclease, was sufficient to show that one should expect one signal per His residue, and that the pK represented not an aggregate pK value but rather reflects the local protein microenvironment. The results were published in a paper that had a dramatic effect on the development of the field of macromolecular applications of NMR.³

In order to confirm this observation I looked for other lysozymes, and found that human lysozyme had then become available. This also had one His residue, so I obtained samples and ran spectra, and found that while there was also only one such titrating resonance, the pK obtained (7.1) was very much higher than that for HEW lysozyme (pK = 5.8), as a result of very different microenvironments for these residues.⁴

In 1969 I joined NIH, where Ted Becker had acquired one of the first 220 MHz spectrometers. Although I was employed in the computer division, I carried out NMR studies of proteins in collaboration with Chris Anfinsen's laboratory. We did one of the first computer curve-fitting analyses of protein NMR data,⁵ and we used NMR and the four His residues of *Staph.* nuclease⁶ to show that individual residues in a protein can exhibit different denaturation midpoints.⁷ We analyzed⁸ and unequivocally assigned⁹ all the four His resonances of RNase, and we also reported the first ^{13}C NMR titration curves of carboxy groups in proteins.¹⁰

After several years of studying protein NMR signals and analyzing their relationship to protein conformation, I saw that major developments were occurring in biological NMR. But, with only 220 MHz and 270 MHz NMR spectrometers with narrow bore magnets available, potential applications were limited. We did some successful studies on chromaffin granules,¹¹ but I wanted to study intact cells. However, following some of the pioneering work of Navon et al.¹² on cell suspensions proved difficult, and the results were very variable. We decided that the reasons were two-fold: first, sedimentation of the cells (unlike the granules that remained suspended), and second, loss of ATP signals in the cells due to the depletion of glucose and oxygen, as well as the acidification due to lactate build-up. In order to overcome these problems, a perfusion system was needed to supply fresh nutrients and remove catabolites. But how to prevent the cells from moving with the perfusate, and use only a standard NMR tube?

At first we tried various kinds of fibers, but they were not good due to the back-pressure and the very slow perfusion/diffusion rates. We also tried microspheres, but they also had major disadvantages not least the loss in sensitivity.¹³ Finally we decided to embed the cells in a gel,¹⁴ but a gel block was not good. So we tried to cut the gel into small pieces and we also tried to mould the gel into small beads. After some experimentation, however, we found that the best means was to make a very fine gel thread by extruding the liquid gel (mixed with cells) through a cooled capillary.^{15,16} This had the advantages that the gel could be packed with cells (thus retaining signal-to-noise ratio) and the small diameter of the thread (0.5 mm) allowed effective access to the nutrients, as we showed by extensive diffusion studies.¹⁷ This method has now been applied for 10 years and many successful studies of cancer cell metabolism have been published.¹⁸

Mildred Cohn: Peregrinations of an Enzymologist in NMR

Mildred Cohn

University of Pennsylvania Medical School, Philadelphia, PA, USA

In the 1950s, Washington University was a center of magnetic resonance with George Pake and Dick Norberg in the Physics Department and Sam Weissman in the Chemistry Department, and news of the developments were transmitted to me by my husband, Henry Primakoff, a member of the Physics Faculty. My research interests at that time focused on the reactions of adenosine triphosphate (ATP), first on the specificity of the obligatory divalent metal ion, e.g. Mg versus Ca, and second on the specificity of the bond cleavage, i.e. what determined whether cleavage occurred on the γ -P of ATP (phosphoryl transfer) or the α -P of ATP (adenyl transfer). Metal ion specificity could be ascribed to metal-dependent structural differences in the metal nucleotide complexes ($M \cdot ATP$) and enzyme-dependent bond cleavage specificity might be ascribed to involvement of different phosphate groups of ATP in the enzyme-metal-ATP complexes ($E \cdot M \cdot ATP$).

I had failed to answer these questions by ESR spectroscopy of the Mn(II) complexes¹ and it occurred to me while on sabbatical at Oxford in 1955 that ^{31}P NMR should be able to distinguish the three P atoms of ATP and consequently define the structure of enzyme-bound $M \cdot ATP$. When I returned to St. Louis in February 1956, I was disappointed to learn that the home-made NMR spectrometer at Washington University was limited to the detection of protons. Consequently I contacted Varian and inquired whether I could try to observe the ^{31}P spectrum of ATP in their Applications Laboratory in Palo Alto. Their reply was most enthusiastic, inviting me to come any time. Due to family obligations, I decided it was not feasible for me to go off to California for an extended period. Two years later in 1958, we planned to spend the summer quarter at Stanford. I wrote to Varian informing them that I was still interested in the problem, inquiring whether I could pursue it that summer. Their reply was grudgingly in the affirmative. In the two years that had elapsed Varian had developed a reliable, stable instrument, increased the magnetic field by 50% (HR-60) and had demonstrated its unique usefulness in determining structures of organic compounds. The Applications Laboratory was overwhelmed by requests from organic chemists for feasibility studies. The biochemists, except for the pioneering work of Oleg Jardetzky on amino acids and dipeptides,² had not yet discovered NMR.

The first Sunday we were at Stanford, we visited our friends the Hofstadters, where I met Felix Bloch. During the visit, Bloch asked what I planned to do that summer and I told him that I hoped to make some NMR measurements at Varian. Whereupon he said I am going to Varian tomorrow, would you like to come with me? Overwhelmed by my good fortune, I answered with alacrity I'd be delighted. On the adventurous trip in his convertible the next day (Bloch's driving habits

were hardly reassuring), he told me that he no longer worked in NMR—it was now chemistry.

In spite of my introduction to Jim Shoolery by Bloch, I did not get to do ^{31}P NMR until six weeks after that initial visit. I did the 1H NMR of ATP the first week, but the Applications Lab was very busy demonstrating the potency of proton NMR to prospective customers, and with only one HR-60 spectrometer available to them they were understandably loath to switch from a 1H probe to a ^{31}P probe. Finally I was granted a day and I brought three incredibly viscous solutions, 1 M ATP, 1 M MgATP, and 1 M MnATP, the concentration necessary to observe ^{31}P in a single scan at 24.3 MHz in a 5-mm tube. That day, I was most grateful to Varian, feasibility of the approach was demonstrated; the spectrum of ATP revealed three well-resolved peaks which shifted with Mg, particularly the β -P resonance, and Mn(II) obliterated all three peaks.

Full of enthusiasm to pursue the problem systematically when I returned to St. Louis, I fortunately learned that the Chemistry Department at the University of Illinois had recently acquired an HR-60 spectrometer with a ^{31}P probe. Through friends at Washington University and at Illinois, arrangements were made enabling me to have the use of the spectrometer on weekends. It was not an easy commute but it was manageable on an interim basis. I extended my original experiments and found, as expected, that the α -P of ADP and ATP had similar shifts and the β -P of ADP and the γ -P of ATP shifts were similar and highly pH-dependent; the unusually high upfield shift of the β -P of ATP confirmed the original observation. Unlike the chemical shifts in proton NMR, there was no theory available to explain the shifts in ^{31}P NMR.

In the meantime, Sam Weissman had been asked to apply for a grant from NIH to purchase a Varian spectrometer for the Washington University Chemistry Department and he invited my participation in the proposal, generously offering me one-fourth time on the instrument. Sometime in 1959, the DP-60 spectrometer duly arrived and Tom Hughes, a physics graduate student, was put in charge. Considerable delay was encountered not only because Hughes was a perfectionist, but because Varian had neglected to include a temperature control for the magnet (temperature changes may not have been a problem in Palo Alto, but in St. Louis the temperature could easily vary by 20 °C in the course of a day). A spectrum of 0.5 M ATP recorded in a single scan on this spectrometer is shown in Figure 1;³ easily resolving the doublet for γ -P, the doublet for α -P broadened by the unresolved coupling to 1H -5' of the ribose and the apparent triplet of β -P, allowing the coupling constants of α - β and β - γ to be determined. To increase the sensitivity, Hughes applied an ingenious method, the opposed sideband technique,³ and succeeded in observing the three peaks of ATP at 0.09 M with good signal-to-noise, albeit in 12-mm thin-walled plastic tubes (containers of Hughes' Havana cigars). Although our ^{31}P probe could maximally accommodate a 12-mm diameter tube, no spinner was available and the nonspinning peaks were very broad. The pH dependence of the chemical shifts of ADP and ATP were determined,³ and we proceeded to study the effects of metal ions.

In preparation for the metal complex experiments, I removed the sodium from the commercial ATP and substituted the tetramethylammonium ion on an ion-exchange column. Much to my surprise and chagrin, the spectrum of this preparation differed greatly from that of sodium ATP, the β - and γ -P

Figure 1 High-resolution ^{31}P NMR spectrum of tetramethylammonium salt of ATP (0.5 M) at pH 10.0. The splitting due to spin–spin interaction is 19.3 ± 0.5 c/s for all the peaks. The two small peaks following the γ doublet are artifacts due to baseline instability and were not observed in subsequent experiments (Ref. 3)

resonances were very broad and the α -P resonance was sharper and enhanced in height. Disturbed, I consulted my chemist friends and Dave Lipkin said, *It looks like a paramagnetic effect*. Whereupon I investigated the history of the resin and found that it had been sized through a brass sieve, the usual procedure at that time. The unlikely supposition that copper had been picked up by the resin during sizing and had been removed by the ATP was indeed confirmed by ashing the ATP sample and analyzing for copper. Because Cu(II) can only form square-planar complexes, only the β -P and γ -P resonances were broadened and the narrowing of the α -P represented the collapse of the unresolved α -P doublet due to the greatly increased relaxation rate of the β -P (the poor man's decoupling technique). In the diamagnetic ion complexes of ADP and ATP (Mg, Ca, Zn), the largest change in chemical shift for all three ions was again the β -P resonance of ATP (3 ppm) with only minor differences among the ions. An attempt to observe an effect of the enzyme hexokinase failed because, as I found many years later, the effect was much too small with such a low ratio of E-MgATP/MgATP.

Upon the urging of Sam Weissman, I submitted a preliminary communication co-authored with Tom Hughes to the *Journal of the American Chemical Society* on the ^{31}P spectrum of ATP and the effect of metal ions thereon. The manuscript was rejected. One referee stated that no chemist would be interested because we had used a commercial instrument and the second referee commented that no biochemist would understand it and suggested that it be expanded into a full paper. I took the latter's advice and published two papers in the *Journal of Biological Chemistry*, one on the pH effect³ and another on the metal ion effects.⁴

In July 1960, I moved from Washington University to the Johnson Research Foundation/Biophysics Department of the University of Pennsylvania. When I arrived I found that there was no NMR spectrometer on campus. I was not too disappointed because I had already come to the conclusion that high-resolution ^{31}P NMR was too insensitive, both in required concentration and magnitude of chemical shifts, to be useful in establishing the structures of metal nucleotide–enzyme complexes. There was an ESR spectrometer in our department and an electrical engineering student, Jack Leigh, under the direction of Britton Chance, was constructing a pulsed NMR instrument which would be suitable for measuring relaxation times of water as developed by Hahn.⁵

The concentration of one component of enzymatic reaction systems, namely water, lends itself readily to NMR measurements and the insensitive chemical shift parameter could be replaced by the highly sensitive effect of Mn(II) on the proton relaxation rates, $1/T_1$ and $1/T_2$, (PRR) of water; 1 M Mn(II) increases the PRR of water approximately 10 000-fold. Mn

can substitute for Mg as the obligatory divalent activator in all enzymatic reactions of ATP. Thus it became possible to measure an NMR parameter of enzyme systems at concentrations in the range of 10^{-4} to 10^{-5} M in 0.1 mL volumes. I expected to determine the number of water molecules remaining in the first coordination sphere of Mn from the decrease in $1/T_1$ as the substrates and enzyme displaced the water ligands in $\text{Mn}(\text{H}_2\text{O})_6$, as occurred when small molecules complexed with Mn(II). Much to my surprise, we observed a large increase in $1/T_1$ in Mn–enzyme complexes. I had to re-examine my naive assumptions.

The following equations describe the dependence of $1/T_{1p}$, the paramagnetic contribution to the longitudinal relaxation rate, on n , the number of water molecules in the first coordination sphere of the paramagnetic ion, on τ_c , the correlation time, and on the frequency ω_I :

$$1/T_{1p} = np/(\tau_M + T_{1M}) \quad (1)$$

where τ_M is the residence time, T_{1M} the longitudinal relaxation time in the first coordination sphere of the metal ion; p is the ratio of the concentration of paramagnetic ions to that of water. For macromolecular manganous complexes, the Solomon–Bloembergen equation for $1/T_{1M}$ simplifies to:

$$1/T_{1M} = B/r^6[3\tau_c/(1 + \omega_I^2\tau_c^2)] \quad (2)$$

where B is a product of physical constants determined by the electron spin of Mn(II) and the magnetogyric ratio of the proton, r is the ion–proton internuclear distance, ω_I is the angular precession frequency of the nucleus, and τ_c is given by:

$$1/\tau_c = 1/\tau_r + 1/\tau_e \quad (3)$$

where τ_r is the rotational correlation time of the water in the hydration sphere and τ_e is the electron spin relaxation time. Eisinger et al.⁶ observed increases of PRR by factors of five to 10 in DNA solutions with Mn(II), Cu(II), and Cr(III); Ni(II) and Co(II) showed no such enhancement (ϵ). Only for Mn(II), Cu(II), and Cr(III) with their long spin relaxation times does τ_r determine τ_c . If the ion is bound to a macromolecule, the rotation of the remaining water in the hydration sphere of the ion is hindered, τ_r increases, τ_c increases and the PRR is enhanced.

The first instrument constructed in conjunction with the ESR spectrometer (0.6 T) had a Varian ^{31}P probe (24.3 MHz) which was borrowed from the Chemistry Department's newly acquired 60 MHz NMR spectrometer. The oscilloscope was perched on a box about 2 ft. above floor level and it could be observed only in a squatting position. This feature was eventually remedied after I complained that I was getting too old for that sort of experimental technique. Polaroid camera photographs of the oscilloscope screen showing signals obtained by the 180° – 90° null method of Carr and Purcell were used to determine T_1 . Our later models of the pulsed NMR spectrometer with a 1.4-T Varian magnet were capable of variable frequency and temperature measurements and a readout of the null point.

When we measured PRR in enzyme systems,⁷ we found that for enzymes which bound Mn(II) at the active site, the values of ϵ in the metal–protein complexes increased more than an

order of magnitude. Furthermore, each ternary or quaternary complex had a unique value of ϵ . We initiated a two-pronged study over the next 15 years to (1) explain the physical basis of the PRR enhancement and (2) understand the implications of the PRR enhancement values for enzyme mechanisms. The first goal was accomplished by studying the PRR as a function of frequency and temperature, and it was found that, in the Mn(II) macromolecular complexes, τ_r becomes so long that τ_c is now determined by τ_e of Mn(II). These measurements were complemented by ESR spectroscopy of the Mn(II)–enzyme complexes as developed by George Reed. The aspects of enzyme mechanisms which could be derived from these measurements were (1) the determination of binding constants and number of binding sites, (2) the differentiation between those enzymes which bind the metal in a binary complex and those which bind the metal ion via a substrate bridge, and (3) after determining τ_c , the number, n , of water molecules remaining in the first coordination sphere of Mn(II) which were in rapid exchange with the bulk water could be calculated for each complex. The generalization which resulted was that as each successive ligand (substrate or product) was added to the enzyme, n decreased, implying that the active site became less and less accessible to solvent. The applications to various enzyme systems have been reviewed.^{8–10}

With the improvement of commercially available spectrometers, the Varian HR-60 was followed by the HR-100, and biochemists began to use high-resolution proton NMR spectroscopy, particularly for structure determination of molecules of biological interest. By the end of 1963, when Arthur Kowalsky and I reviewed applications of NMR in biochemistry,¹¹ there were 140 relevant papers in the literature, almost all published between 1960 and 1963. In the mid-1960s through the 1970s, we began exploring once again the possibilities of using high-resolution NMR to elucidate enzyme mechanisms. For example, Mildvan and Leigh initiated the mapping of ligand geometry at active sites of kinases by determining distances from Mn(II) to various atoms in the enzyme-bound substrates from the effect of paramagnetic Mn on the relaxation rates of the nuclei of those atoms; narrowing of proton resonances in macromolecules was attempted. In the 1970s, the stereochemistry of the enolase reaction was determined by combined ³¹P and ¹³C measurements; an intermolecular NOE effect between a ligand proton and a lysyl residue on creatine kinase was observed; and the proton NMR of the enzyme adenylate kinase was investigated at 220 MHz.

Finally we returned to the original problem, and Nageswara Rao investigated the changes in the ³¹P spectra of MgATP and MgADP upon binding to stoichiometric concentrations of enzymes and in equilibrium mixtures of enzyme-bound substrates and products. The most striking finding was that regardless of the value of the equilibrium constant of the overall reaction which, for the kinase reactions investigated, ranged over four orders of magnitude, the equilibrium constant for the central complexes $E \cdot S_1 \cdot S_2 \rightleftharpoons 2; E \cdot P_1 \cdot P_2$, was

always close to 1. From lineshape analysis, the rate of this step could also be determined and it could be established whether it was the rate-determining step in the overall reaction. The results of this series of experiments have been reviewed.¹² Other aspects of enzyme mechanisms were examined with ³¹P NMR by substitution of ¹⁶O in phosphate groups by either ¹⁸O¹³ or by sulfur.¹⁴

In recent years there has been an unforeseen explosion in applications of NMR in biomedical research resulting from spectacular technological developments. High-resolution proton spectroscopy at 500–600 MHz is the most informative method for studying protein structures in solution, ³¹P is the nucleus of choice for most in vivo studies, and PRR of water is the most used parameter of MRI.

Corio, Paul L.: High-Resolution NMR at Columbia University

Paul L. Corio

University of Kentucky, Lexington, KY, USA

I began my second year of graduate study working with Richard Noyes on a problem in chemical kinetics, my first task being the synthesis of a cyclic compound containing two adjacent sulfur atoms. After some disquieting experiences with superheated steam coursing angrily through a crudely constructed still, I obtained about 50 mL of product, a clear, viscous liquid, which polymerized overnight. I rolled the pliable polymer between my palms into a sphere and, bouncing it, discovered that it had a remarkably high coefficient of restitution. A few days later, however, a persistent, irritating rash erupted on both hands, rendering further chemical research impossible. I thought about physics or mathematics, but a friend persuaded me to speak to Ben Dailey, who had just spent a summer working with Jim Shoolery at Varian Associates in Palo Alto. Dailey was enthusiastic about NMR, and wanted to build a spectrometer, starting with a few pieces of commercial equipment and some circuit diagrams provided by Varian—but no magnet! With gloves protecting my bandaged hands, we built the simpler components. Someone at the Watson Laboratories of IBM graciously consented to let us use a Varian 12 in. magnet, so we hauled our nondescript creation over to the laboratories on 115th Street where, to my astonishment, it worked.

There were several notable physicists associated with the Watson Laboratories at the time: Llewellyn H. Thomas, Leon Brillouin, Erwin Hahn, and, somewhat later, Alfred Redfield. Hahn gave some lectures on magnetic resonance which were quite good, but that was a judgement I was only able to make on looking over my notes long after the course was over. Hahn's students were doing spin echo experiments, unfortunately at the same frequency as our high-resolution experiments, and their rf pulses cut through our spectra like a chain saw. The only solution was to work evenings, which had the further advantage that the line voltage settled down. One afternoon, however, I stepped into the laboratory and discovered Hahn behaving very strangely. He stooped before the 12 in. magnet and, still stooping, waddled up to the magnet like a duck, all the while twirling a small, metallic loop with his forefingers, rotating one finger about the other. When he reached the magnet, he stopped for a moment, then, still stooping, waddled backward, this time reversing the twirling motion of his fingers. I decided that it would be wise to leave, when Hahn stood up and, noting my evident dismay, hastily explained he was trying to demagnetize his watch by taking it through a hysteresis loop. When my watch was subsequently magnetized, I tried Hahn's procedure—late at night, when no one was about. It didn't work. I don't believe Hahn ever had the right time.

Dailey and I started looking at the spectra of monosubstituted benzenes, and though our interpretations were qualitatively correct, improvements in resolution were so remarkable

within a few months that I couldn't bear to look at spectra that once seemed beautiful. Field inhomogeneity was the principal problem, and Ben got the money for a new 12 in. Varian magnet, which had to be hoisted to the eighth floor of the Chandler Chemistry Laboratories. A pulley system was rigged upon the roof, and a winch in the back of a small pick-up truck started hoisting the magnet skyward. As the magnet rose, so did the tail end of the truck, to an angle of 30 ° when the magnet was four stories high. The lift was not successfully accomplished until a half-dozen workmen mounted the rear of the truck.

After we were established in our own laboratory, resolution improved markedly, and I became interested in understanding the fine structure we were observing. The papers from which I profited most were those of Hahn and Maxwell,¹ Gutowsky, McCall, and Slichter,² and Anderson.³ The papers by Hahn and Maxwell gave the first exact calculations for what are now known as the AB and A₂B systems. The calculations were simple examples of matrix mechanics, and I began an assiduous study of the problem, interrupted only when Dailey arranged for me to spend some time at Varian Associates, where I met Wes Anderson and Jim Shoolery, and, at Stanford, Jim Arnold (whose permanent magnet set an extraordinary standard for resolution) and Felix Bloch. Wes Anderson was working on the application of the moment method to high-resolution spectra, and I calculated the moments of *o*-dichlorobenzene for him with a planimeter. I've always thought the moment method was the most elegant approach to spectral analysis; unfortunately, error accumulation in the determination of the higher moments is considerable. When I returned to Columbia, I worked out the details of the method and gave a seminar on it, using a strongly coupled three-spin system as an example. The method was subsequently published by Anderson and McConnell,⁴ but the development I gave in a review article⁵ is essentially Anderson's original version.

The most useful results of my work on high-resolution spectra were the proofs of a few theorems, the first use of computers in the analysis of spectra,⁵ and the decomposition of a complex spectrum into the superposition of the spectra of its irreducible components,^{6,7} leading to the complete or partial analyses of some spectra by inspection.

Later, at the Paulsboro Laboratories of the Mobil Oil Corporation, Irving Weinberg and I set up an extremely stable high-resolution system operating at 40 MHz. We installed an independent water supply to the magnet and used a motor generator to provide a stable line voltage. A large, wooden box with a door of transparent plastic enclosed the magnet, and had small circulating fans inside the box to eliminate temperature gradients. With this system, together with cycling magic and humble invocations, we were able to resolve line spacings between 0.2 and 0.3 Hz, before the advent of superstabilizers.

Cotts, Robert M.: Historical Recollections

Robert M. Cotts

Cornell University, Ithaca, NY, USA

Two main themes in my experimental work in NMR have been (1) translational diffusion and (2) metal–hydrogen systems. These are compatible in that, because of its low mass and relatively small size, hydrogen has a high mobility in metals. Because of space limitations this article covers primarily these two themes with regrettable omissions.

Walter D. Knight introduced me to NMR when I joined his research group early in 1952 at the University of California, Berkeley. In addition to learning to use their CW NMR spectrometer, built around a Pound–Knight marginal oscillator, I built a similar spectrometer for looking at ‘pure nuclear quadrupole resonance’, NQR. There was considerable interest in perovskite ferroelectrics, and I found the ^{93}Nb ($I = 9/2$) resonances and measured the NQR interaction parameters in two solid state phases of KNbO_3 , including observing the transition to its nonferroelectric cubic phase.¹

I then joined Felix Bloch’s group as an Instructor in Physics at Stanford University. With George Pake there on leave from Washington University, and a short visit from E. Raymond Andrew from the UK, line narrowing processes were frequently discussed. Graduate student Lynn R. Sarles and I did a spin decoupling experiment on solid NaF, looking at the ^{23}Na NMR at low power using a marginal oscillator while driving the ^{19}F spins with a 100 W, modified military rf transmitter operating at 17 MHz. Emphasis was on the second moment of the Na resonance.² All second moments were obtained by double integration (by hand) from the first derivative of the lineshape on chart paper.

After my move to Cornell University in 1957, graduate student David H. Smith built another CW spectrometer and he grew some good single crystals of thiourea, $\text{SC}(\text{NH}_2)_2$, an organic ferroelectric for a study using ^{14}N NQR and ^1H NMR. A second student, David S. Schreiber, started a project on NMR of lanthanum metal and its alloys to measure Knight shifts in normal and superconducting states. Pure La was hard to obtain. In tracking down the reason for observing a second, shifted La resonance line, he identified it as an impurity, LaH_x . We found this hydride so interesting that it became the project and yielded an abundance of evidence on H atom siting, Knight shifts, a metal–insulator transition, and the effects of H atom motion on both the ^1H and ^{139}La NMR lineshapes and relaxation rates.³ Schreiber built a 1 kW pulsed spectrometer based on the one well-designed and developed at Cornell by W. Gilbert Clark, a student in Donald F. Holcomb’s group. In addition to analyzing ^{14}N NQR in thiourea, Smith used the pulse rig to observe a deep T_1 minimum in ^1H due to molecular reorientation, and demonstrated cross relaxation between ^1H and ^{14}N systems by field cycling experiments.⁴ The pulse rig became a laboratory work horse and made many new NMR experiments possible.

I was attracted to the sensitivity of NMR and its use to study atomic motion. David Zamir came on a postdoc from Israel, and in studying diffusion effects of H in NbH_x , he found

that at high temperatures the transverse relaxation rate, T_2^{-1} , did not equal T_1^{-1} as it should.⁵ From Carr–Purcell pulse trains, the additional rate was identified as attenuation of the ^1H spin echo due to H atom diffusion in field gradients caused by susceptibility broadening in the necessarily small metal particles.⁶ Thinking about diffusion in small volumes triggered Richard C. Wayne’s studying effects of ‘reflecting’ planar boundaries on diffusion coefficient measurements made using constant magnetic field gradients. As his working substance he used gaseous methane at about 6 MPa.⁷ This work stimulated Baldwin Robertson’s calculations on restricted diffusion⁸ and C. H. Neuman to publish his useful analytic approximations.⁹

James S. Murday built a current source for pulsed field gradients (PFG) and measured the diffusion isotope effect in liquid lithium. He extended Neuman’s restricted diffusion theory to the PFG experiment and used the results to correct his data to compensate for finite-sized Li spheres. He also developed means to correct for systematic errors due to background gradients.¹⁰ Of course, visitor Olgierd J. Zogal had no such corrections to make on his D measurements on a 6-mm diameter single crystal of $\text{NbH}_{0.6}$.¹¹ Based on these developments, plant science student Darryl G. Stout devised a way to use PFG echo dependence on gradient strength under highly restricted diffusion conditions to measure the water permeability of membranes of the spherical, small cells of *Chlorella vulgaris*.¹²

Continued concern about systematic errors from background gradients in metal hydride particles led W. David Williams and our collaborator Edward F. W. Seymour from the UK to invent a way to eliminate the nuisance ‘cross term’ in PFG echo analysis by finding a way to insert the PFG pulses into Carr–Purcell echo trains.¹³ Later at Pittsburgh, R. F. Karliceck and I. J. Lowe (KL) found a better way using bipolar gradient pulses. They persuaded us, so Philip E. Mauger built a bipolar pulser of his design and a new pulse rig to measure H diffusion in Group V transition metal hydrides.¹⁴ Elena Sevilla used the KL technique to show the importance of crystal structure in that diffusion parameters are about the same for H in bcc Ti as for other bcc host lattices.¹⁵ Because of the T_2 shortening, the stimulated echo has advantages in PFG experiments, and here with the Johannesburg visitor Michael J. R. Hoch’s help, several schemes for reducing and eliminating the ‘cross term’ were developed and demonstrated.¹⁶

We developed growing interest in more accurate¹¹ calculations for determining the mean residence time, τ_d , from relaxation rate measurements. With reliable τ_d values, and independently measured D values from PFG experiments, one could see whether the ‘step length’ was consistent with an assumed diffusion mechanism. Larry D. Bustard measured both D and τ_d of H in cubic TiH_x to settle an issue over whether H atoms indeed jumped to the nearest neighbor site. Bustard independently developed his Monte-Carlo simulation of atoms hopping on a simple cubic lattice to calculate the pair correlation functions needed to determine τ_d from relaxation data, and he showed that H jumps are to nearest neighbor sites.¹⁷ In a test of such detailed understanding, postdoc Nouha Salibi experimentally confirmed the $\omega^{1/2}$ dependence of T_1^{-1} at low NMR frequencies.¹⁸ My last student, Andrew F. McDowell, substantially extended the Monte-Carlo simulation to H in the metallic glass NiZr_2H_x , to see how a realistic distribution of site and/or barrier energies affect the NMR relaxation peak curves, and

in comparing these to his experimental data, demonstrated the special importance of barrier energies.¹⁹

Crooks, Lawrence E.: Field Strength Selection for MR Imaging

Lawrence E. Crooks

University of California, San Francisco, CA, USA

INTRODUCTION

I joined the University of California San Francisco's Radiology Department in 1976 to work on NMR imaging (later MR imaging). The first task was to get a new Varian 4-in. gap electromagnet working and produce rat images. The magnet was designed to operate at 0.35 T for its specified homogeneity. This magnet was similar to one used by Hinshaw at Nottingham to produce animal and wrist images¹⁻³ at 0.7 T. He used ac gradients to produce sensitive points and lines. These sensitive point and line scans were my first choice of technique since I had inherited a continuous wave (CW) system. Although the CW nature of the ac gradient imaging was a good match, the ac gradients were incompatible with the field modulation required by the lock-in-amplifier output section of the receiver. I eventually used a sensitive point technique like Damadian's^{4,5} to image phantoms and a rat by moving them through the sensitive point.⁶ These crude images were sufficiently impressive that the laboratory director, Leon Kaufman, convinced Pfizer Medical Systems to support our development of a whole body imager.

I began the simultaneous design and construction of a pulsed FT electronics package and the search for a suitable human-sized magnet. My experience was with electromagnets at 0.23 T (with J.R. Singer) and the Varian unit above. I detested the field drift of these units and considered a field stabilizer in the presence of pulsed gradients to be a tougher problem than I wanted to solve. The typical human-sized imaging magnets of the time were four coil resistive air core units. Lauterbur was using one, the Aberdeen group was building one, and one group at Nottingham had one on order. These covered the 0.05–0.15 T field range.

CONCEPTUAL LIMITS ON FIELD STRENGTH

In guiding our choice of field strength we had Hoult and Lauterbur's paper⁷ on signal-to-noise ratio (S/N) versus field strength as a start. It indicated a 10 MHz maximum (0.23 T) for body imaging. Next was Bottomley's paper⁸ on rf penetration into uniform conducting cylinders. Its graphs indicate rapidly increasing penetration loss between 10–30 MHz. My experience at 10 MHz and 15 MHz was positive and a head-sized saddle coil we built would tune at 15 MHz with reasonable capacitors. We thus decided to attempt 0.35 T with the thought that we could reduce the field strength if it was too high.

MAGNET SELECTION

We began our search with Varian, who proposed an iron core electromagnet (like the animal imager turned on its side) scaled to human size. Their first thought was that their usual Rose shim would require a 56-in. diameter pole tip to achieve the same homogeneity (in ppm) as our animal imager over a head size volume. They considered this too large to handle and would investigate better shimming methods. Fortunately we never pursued this any further.

At this time I attended the 19th ENC in Blacksburg, VA (April 1978) to hear reports on progress by Damadian, Hoult, Lauterbur, and Mansfield. During the meeting I met Richard Woods from Intermagnetics General Corporation. Mr. Woods was an enthusiastic proponent of superconducting magnets for imaging. IGC had built a 2 T monkey-size magnet for Joe Battocletti's blood flow research. Although our size and homogeneity requirements were much better than that magnet, he thought both were achievable and our field strength rather modest. When I asked about field stability, the persistent superconductor was exquisite compared to any other magnet type. At that year's Gordon Research Conference (August) I met Derek Shaw from Oxford Instruments, Oxford. Dr. Shaw was much more conservative about superconductive magnets since Oxford was working on four coil resistive air core designs. After returning to England he later contacted us with a superconductive design proposal.

Our contacts at Pfizer Medical Systems were pleased with the superconducting magnet idea. One thought it sounded so sexy that no doctor would pass it up. The usual concern we encountered within our radiology department was 'You're going to have cryogenics in the hospital!?' That did not seem to concern Pfizer and we proceeded to visit Oxford and IGC to review the designs and so that Pfizer could assess the companies. Based on business and technical aspects, Pfizer decided to order a magnet from Oxford for placement in our laboratory. Oxford at the same time built a similar magnet for EMI that was placed in Hammersmith Hospital. It worked before ours, but at 0.15 T.

During the year and a half construction and installation period, we used our pulsed FT system to image rat populations with induced diseases in the Varian magnet. We measured T_1 and T_2 of normal and abnormal tissue to begin quantifying the disease detection characteristics of MR imaging.⁹⁻¹¹ We refined imaging techniques and electronics in anticipation of the arrival of the bigger magnet.

Once the magnet was working, we had the challenges of getting the Oxford gradient power supplies to behave and then compensate the eddy currents, and getting rf coils to work effectively. We still have today the copper mesh screen room we built to house the imager. The room included the gradient power supplies since that was easier than building filters that removed rf from the gradients but would not make the power supplies oscillate.

IMAGING RESULTS

Our first head image was a line scan on 7 March 1981. We had concentrated on line scanning because of Leon Kaufman's concern that 'reconstruction' methods would suffer the nasty motion artifacts prevalent in X-ray CT at that time. The S/N

advantage of two-dimensional Fourier transform (2D FT) MR imaging^{12,13} and its wider contrast range than X-rays turned out to hide these artifacts. I converted to 2D FT imaging with a 10-times gain in S/N.

These were good images compared to what others were achieving.^{14–19} Measuring gray and white matter relaxation times provided refinements to image contrast. Human abdominal imaging used the relaxation times from our rats. Ongoing improvements in rf shielding and coils, and eddy current performance got us to great image quality level by November 1981.^{20,21}

Our demonstration of the lack of rf penetration problems and effective head and body coils at 15 MHz with superior S/N began a race to ever higher field strengths. Increasing field strength gained S/N as rf coil performance improved. However, changing relaxation times and chemical shift detract from the image quality so that the actual improvement is less than expected. These topics have been actively debated.^{22–26}

CONCLUSIONS

Today the most common field strength is 1.5 T with 0.5 T gaining in popularity. Head imaging at 3 T and 4 T is gaining interest for functional brain imaging²⁷ due to the dependence on magnetic susceptibility. At these frequencies, rf penetration and dielectric resonances are appearing, so we are encountering some of the expected limits. Instead of going to higher field strengths, our laboratory moved down to 0.065 T. This gave a less expensive more open imager.²⁸ The challenge is to extract the most S/N and take advantage of the shorter T_1 relaxation times of tissue to improve disease detection.

The high-field race occurred in an environment of performance at any price. Today health care reform is increasing the emphasis on economics. This may slant the choice of imagers to lower field strengths that are today as diagnostically effective as higher field imagers were a few years ago.

Dadok, Josef: High-Field NMR Instrumentation

Josef Dadok

Carnegie Mellon University, Pittsburgh, PA, USA

INTRODUCTION

In 1957 I entered the field of NMR instrumentation while working at the Institute for Scientific Instruments of the Czechoslovak Academy of Sciences in Brno, Czechoslovakia. There I headed a group engaged in building a microwave spectrometer for the 1.25 cm K-band. At that time it was very difficult to obtain components for the K-band in Czechoslovakia (they were on the embargo list) and therefore my deputy O. Chramosta and I both welcomed the proposal by Otto Knessl of the Institute of Organic Chemistry and Biochemistry of the Czechoslovak Academy of Sciences in Prague, to switch to building an instrument for which the resources were available at home. Using the literature and a few ideas of our own, we went through the usual sequence of troubles and frequencies and we were able to produce high-resolution spectra at 30 MHz in 1960, at 40 MHz in 1962, at 60 MHz in 1964, and at 80 MHz in 1967. The technical documentation was given to a company named TESLA BRNO and Czechoslovakia became the only supplier of high-resolution NMR spectrometers for countries in eastern Europe.

We had many amusing experiences during that time, but one of them is perhaps noteworthy. After we observed the first spectra of ethyl alcohol on the screen, it was obvious that the stability of the magnetic field was not as good as the stability of the current we supplied to the magnet. Very soon we started to suspect the line of a trolley bus in our street. Quick calculations revealed that one bus alone could not produce the size of the observed variations and that probably a common cable for more lines had to be there. The supervisor of the city network denied this and therefore we decided to find the source ourselves. Equipped with a big coil with many thousands of turns and with a sensitive galvanometer, we stepped out into the streets and followed the source of magnetic fluctuations. After about half a mile, we ran into a control station for the trolley system and there on the wall we found a diagram that confirmed our suspicion. Obviously, we had talked before to the wrong person. We fixed the problem in two ways: first, we moved to a new location which was at least 200 meters away from another streetcar line and second, we built a flux superstabilizer using a chopper stabilized dc amplifier. Even then we could tell when a train left the closest station by observing the change in the bucking coils current.

SOME 'NEW' IDEAS

At the start of our effort, an external field/frequency lock was being used for long term stabilization and it occurred to me that an internal lock would do better. Using the theory

of modulation techniques, I designed an original scheme of homonuclear internal field/frequency lock, only to find out later that Primas,¹ and probably many others, had the same idea.

In the early 1960s I started to work on my Ph.D., thesis concentrating on the factors that limited the sensitivity and resolution of an NMR spectrometer. I studied the lineshape in an inhomogeneous field and, to my surprise, I found an analytical solution for the distribution function of the resonant frequencies of a cylindrical sample in a field with a fourth-order inhomogeneity.^{2,3} In combination with the finite length of the receiver coil, it was possible to explain exactly the origin of the so-called 'satellite' at the side of a strong single line which often troubled us during shimming. Around about that time I was trying to visit the USA and participate in the ENC conference in Pittsburgh, but I was never able to obtain an exit visa. It was therefore very rewarding to meet Jim Shoolery, who visited Prague in 1964 and who, of course, was fully qualified to evaluate our work.

In 1965 I sent two abstracts to the ENC but again in vain. Finally in 1966 with some help from the President of the Academy, I was allowed to come to Pittsburgh and that changed my whole life. Three other developments were responsible for that change: Harry Weaver's success in building the first NMR magnet using superconducting wire, my meeting Aksel A. Bothner-By, and then later the Soviet invasion of Czechoslovakia.

HIGH-FIELD NMR AT 250 MHZ

The introduction of superconducting magnets into high-resolution NMR shifted the 'high-field' border above 100 MHz for protons.⁴ The need for cryogenics was obvious and it happened that Czechoslovakia was manufacturing helium liquefiers designed originally by the Soviet scientist Kapitsa. I was somewhat discouraged when I saw it, because the liquefier was a big monster. Nevertheless, we started to build a low-temperature laboratory at our institute in Brno (there were plans to use superconducting coils in another major project: electron microscopy) and I was supposed to return to the USA to learn about superconducting magnets for NMR. In October 1967 the political situation was heading toward 'Prague's Spring 68', and I went for a 1 year fellowship to the Mellon Institute in Pittsburgh. As it turned out, I never made it back.

A. A. Bothner-By was heading an NIH NMR facility at MI and wanted to build a high-field spectrometer for 'other' nuclei. It was supposed to be the first shared high-field instrument serving Mellon Institute, University of Pittsburgh, and Carnegie Institute of Technology. He was not able to purchase a suitable superconducting magnet anywhere at that time and decided to take an offer from Westinghouse, where superconductivity was a major R&D project. I was given the task of designing the spectrometer and Richard Sprecher joined us in the overall effort. It turned out that Westinghouse did not have the expertise in high homogeneity magnets and so I found myself very soon not only involved in the mapping of the field, but also in redesigning the main coil and in the design of the superconducting shim coils.⁵

The result was a relatively small persistent magnet for a 250 MHz spectrometer and it was equipped with four superconducting shim coils. After adding 10 room-temperature

Figure 1 The first 250 MHz high-resolution NMR spectrometer with persistent superconducting magnet and removable current leads

shim coils and an internal field/frequency lock system, we actually ended with a high-resolution spectrometer with resolution better than 0.1 Hz. This was in 1969 and we proudly presented it at the 11th ENC (1970) as the highest operating frequency spectrometer in the world.⁶ Only hours later Varian announced their first results at 300 MHz.

During the work on the 250 MHz system we had a very nice collaboration with Frank Anet from UCLA, who was building a 251 MHz system (magnet from Magnion) and with Rex Richards from Oxford University, who was building a 7 T system for ^{31}P spectroscopy (magnet built by Oxford Instruments). Both systems were eventually brought to operation and this probably marked the beginning of the domination of the superconducting NMR magnet market by Oxford Instruments.

Besides the design of the shim coils, based on ideas published by W. Anderson,⁷ I also applied in a more extensive way the time sharing pulse modulation introduced originally by Arnold.⁸ A set of exchangeable receiver coils of our design and a set of exchangeable filters provided the multinuclear capability. Rich was trying to optimize the dimensions of our magnet leads and he found (not surprisingly) that the best leads are no leads at all. He therefore designed the first removable leads in an NMR magnet and we started to operate the facility quite routinely. With 0.1 L of liquid He needed per hour, we had to refill once every 4 days.

The spectrometer (Figure 1) was a success and many scientists from around the world came to use it. With the built-in (sometimes too much) flexibility, we could provide spectra

of almost any nucleus. It was still the time of predominantly CW techniques but the writing was already on the wall.

SPECTRUM CONTAINING ONLY SPINNING SIDEBANDS

Because of our extensive use of a single receiver coil system, and because of the less than ideal homogeneity of our rf and static fields, we observed some unusual behavior of the spinning sidebands. By more detailed analysis⁹ we were able to show, that in the presence of B_0 and B_1 inhomogeneity, one inhomogeneity can actually compensate for the other. We could then state that the best nonspinning lineshape does not give the smallest spinning sidebands and that the shape of spinning sidebands depends on the direction of spinning and on the sign of the magnetogyric ratio, γ . To check the ideas we then proposed an experiment in which the center band disappears after the spinning of the sample is started. This was achieved by orienting a saddle-shaped coil with B_1 along the z axis in an electromagnet. The only NMR signal generated in that way comes from the x component due to B_1 inhomogeneity and it is almost 100% modulated during spinning of the sample. Many of our colleagues were puzzled and amused when confronted with this experiment.

RAPID SCAN CORRELATION NMR

During the late 1960s, pulsed FT NMR was taking over and it was obvious to us that we needed our own computer. Thanks to the cancellation of another project at Purdue, NIH gave us, in 1971, a modern small mainframe computer, an XDS SIGMA 5. It probably was the first 32-bit computer dedicated fully to NMR. The memory was of a somewhat limited size (64 kb) but it had a relatively fast floating point processor. At that time a digital computer was somewhat opaque to me, but Rich was able to handle it with ease and soon we were trying our first pulsed FT experiment. R. Ernst had just published a paper on stochastic excitation in NMR¹⁰ and Rich thought that we should try it. We immediately ran into a problem: our analog hardware was built for CW and therefore it was narrow-banded. I was browsing through the mathematics of the general Fourier transform theory, realizing that to the first approximation we were looking for the transfer function of a quasilinear system. According to textbooks, this can be done in practice either by slow frequency sweep, pulse excitation followed by FT, or by noise excitation using cross correlation.¹¹ Theoretically any excitation will do, if it has the proper spectral density function. By intuition I felt that a rapid frequency sweep could have some advantages, but to my surprise I could not find any references in the available literature. I mentioned this 'Gedankenexperiment' to some of my colleagues, but except for Richard Ernst, I mostly met with doubts.

I tried to go through the exact mathematics of such an experiment, but before finding the full analytical expression I saw that cross correlation of two Lorentzian lines recorded with identical sweep rates with 'wiggles'¹² will give a new Lorentzian line without wiggles and of a linewidth given by the sum of the original two lines. Rich promptly wrote the necessary software and in February 1972 we were recording

the first rapid scan correlation spectra at 250 MHz using a chloroform line as the reference. In the next step Rich calculated the theoretical reference line by integrating the Bloch equations. We presented this at the 13th ENC¹³ and started to refine the technique while slowly preparing the publication. By digging deeper into the description of the action of the synchronous detector under the rapid scan, I was able to provide Rich with the expression for the zero-width reference line in the frequency domain:

$$R(\omega) = e^{-j \frac{\omega^2}{2a} \text{sgn } \omega} \quad (1)$$

where a is the sweep rate. This of course simplified the calculation and we continued to add other refinements like resolution enhancement, difference spectroscopy, and others. We learned in the meantime that G. A. Petersson used a line with wiggles for optimum filtering and for sensitivity or resolution enhancement in his thesis.¹⁴ We did not know that after the 13th ENC another group at NIH was intensively working on the detailed theory of the rapid scan experiment¹⁵ and, only after we found out, submitted our communication in a hurry.¹⁶ After that, we used the rapid scan technique extensively and solved along the way many small problems connected with digital frequency sweep, sampling, filtering, homonuclear lock, etc.

To eliminate some truncation problems, we later chose to calculate the theoretical reference line from the time domain response of an infinitely narrow line to rapid scan, which is given by the Fourier transform of equation (1).¹⁷

$$r(t) = \sqrt{\frac{a}{\pi}} \left[\cos \frac{1}{2} at^2 \left(\frac{1}{2} + \text{sgn } t \times C_2 \left\{ \frac{1}{2} at^2 \right\} \right) + \sin \frac{1}{2} at^2 \left(\frac{1}{2} + \text{sgn } t \times S_2 \left\{ \frac{1}{2} at^2 \right\} \right) \right] \quad (2)$$

Here C_2 and S_2 are Fresnel integrals. A similar formula was first derived by Bitter et al.¹⁸ from the Bloch equations.

Using this technique for 1D spectra offers some advantages such as low rf transmitter power, very selective tailored excitation and simple water signal suppression, but for 2D spectroscopy the pulse technique is without competition. There were attempts to incorporate the rapid scan correlation technique into commercial spectrometers, but not with much success. Only Hitachi is using it now in a simple field sweep 60 MHz instrument. We were using it exclusively at 250 MHz and are using it routinely even now at 620 MHz for some experiments.

HIGH-FIELD NMR AT 600 MHZ

While the 250 MHz spectrometer was in intensive use from 1969 to 1978, we were thinking about a new project, possibly at higher fields. As sometimes happens, at the same time General Electric was looking for some new applications of their recently developed Nb₃Sn superconducting tape. In September of 1970, their market development manager Paul Swartz sent us a letter with a piece of Nb₃Sn tape attached to it, and informed us that they could build a nonpersistent superconducting magnet for us with a field of 11.75 T. At

that time the commercially available NMR magnet was 7.05 T. When we confronted Paul with the demands for homogeneity and stability of an NMR magnet, he admitted that this was too much for them at that time. But he was back two years later as the vice president of the GE spin-off called Intermagnetics General Corporation (IGC) with a proposal for a magnet, where the stability problems would be handled by a superconducting cylinder in the bore. It would provide some sort of flux stabilization while using a current supply of high stability and an NMR feedback. In the meantime a 360 MHz Bruker system with an Oxford Instruments NbTi persistent magnet was in operation at Stanford and therefore we proposed to raise the field as high as possible.

IGC agreed to move the field up to 14.1 T (600 MHz for protons) and in the summer of 1975 we were able to get the first phase of the funding from NSF. This was a surprise to some members of the NMR community, because they were convinced that there was no way to achieve the necessary stability and homogeneity for high-resolution NMR with a superconducting magnet utilizing Nb₃Sn tape.

In the following three years IGC provided the tape and magnet technology (Dennis Markiewicz, Ed Mains, and Mike Hennessy) and we helped with the problems of homogeneity and stability. We also supplied an improvised 600 MHz NMR spectrometer for testing at the IGC site. The flexibility of our 250 MHz system was then a big advantage.

The IGC magnet was made of 32 pancakes, each pancake containing two ribbon-wound coils with two leads on the outside (Figure 2). The tape itself was superconducting but

Figure 2 The IGC team checking the coils of the 14 T nonpersistent magnet (Reproduced by permission of Intermagnetics General Corporation)

Figure 3 Resolution and short-term stability test at 600 MHz using the rapid scan correlation technique: (a) signal from the CH_3 triplet in 1% ethylbenzene under rapid scan at 1 Hz s^{-1} ; (b) reference line calculated from equation (2) but truncated to prevent violation of the sampling theorem; and (c) spectrum resulting from cross-correlation between (a) and (b)

the many joints were not. The flux stabilization using the superconducting cylinder did not perform sufficiently well because of the mechanical stresses on the cylinder, and therefore we decided to go the classical way known from electromagnets. We monitored the voltage across the magnet and through electronic feedback suppressed the changes of the total magnetic flux. The superconducting shimming of the magnet was difficult, especially for the transverse gradients due to the reaction currents in the tape, and hence we abandoned it completely. The homogeneity was adjusted by changing the calculated separation of the pancakes and by the fine tuning of the small central gap. The remaining inhomogeneity was then corrected by a set of room temperature shim coils. By making the receiver coil relatively short (and paying the price of somewhat lower sensitivity), we were able to get quite good resolution. The first spectrum was recorded in April 1977 on the factory floor using a ^{31}P sample at 243 MHz.¹⁹

The first proton spectra at 600 MHz were recorded in December 1977,²⁰ and in 1978 we presented the results at two international NMR conferences, in England²¹ and in Japan.²² In York, J. W. Emsley introduced us as the winners of the 600 MHz race. In Nara, Kurt Wüthrich introduced Aksel and me to Felix Bloch and told him what we were doing. His quick

comment was: 'I always thought, why don't they go to higher fields?'. By that time the commercial persistent magnets had moved up to 400 MHz.

The final stages of refinement and transfer into a new Dewar were made in 1978 and we moved the magnet to Pittsburgh in February 1979. We started to offer routine spectra at 600 MHz very shortly after that. The resolution (0.15 Hz) and stability were excellent (Figure 3) although we would have enjoyed better sensitivity and smaller spinning sidebands. The conversion from 250 MHz to 600 MHz was done by frequency shifting, using mixers and filters, and in the first two years we operated in the rapid scan correlation mode.²³ In December of 1979 we presented the results and the capability of our instrument to the NMR community at a symposium where users shared their own experiences. Bruker used this opportunity to show the first FT spectra taken at 500 MHz utilizing the latest Oxford Instruments persistent magnet.²⁴ Our first FT system was put together using an old Bruker WH-90 console with the Aspect 2000 computer. Obviously our first IF frequency was 90 MHz and in 1981 we joined the 2D community.²⁵

At that time Mellon Institute suffered many power failures and even a short failure would bring the field down. We therefore designed protective circuitry which would place a short across the magnet and produce a time constant of many hours. Once we installed the protection, Murphy's law stepped in and the power failure occurred only twice during the next 10 years.

The price for the nonpersistence was liquid helium consumption of 0.95 L h^{-1} and with our 65 L reserve it meant filling three times a week. In 1982 we installed our own helium recycling hardware which I liked to call 'an inexhaustible source of entertainment and education', but we were able to cut the cost of operation substantially. With the production rate of 4 L h^{-1} we ran it for three days per week. It is obvious that a persistent magnet has many advantages (low liquid He consumption and easier use for long n -dimensional experiments) and consequently besides Oxford Instruments there were other efforts to build them. John Williams at the Francis Bitter National Magnet Laboratory at MIT had solved the problem of persistent joints for high fields among others and eventually built 500 MHz (1979) and 600 MHz (1989) NMR magnets while operating at somewhat reduced temperature (3 K and 2.5 K). It seemed to us, however, that for achieving the highest possible field at a given time the nonpersistent magnet had an edge, and we were able to show that it can be used successfully for high-quality, high-resolution NMR.

In 1985 we bought a Varian 4000 data acquisition console with a Zeta plotter. The new software was more flexible and allowed us to run phase sensitive 2D.²⁶ For the off-line processing we chose later a Sun Sparcstation computer with the Hare Research Felix program and a 600 dpi laser printer. All the time the laboratory was operating under the name 'NMR Facility for Biomedical Studies' and was supported by NIH until 1990.

For more than eight years this was the only 600 MHz NMR spectrometer in the world. It served in a similar way as the 250 MHz instrument before it, i.e. by providing access to high-field NMR for many scientists from around the country (and some from overseas) who were willing to come to Pittsburgh or at least to send us their samples. A large number of collaborative projects developed, mainly in biochemistry

Figure 4 Portion of the 620 MHz COSY (solid contours) and NOESY (dashed contours) spectra, showing sequential assignment for the choline receptor peptide fragment KESRGWKHWVFYA (from a collaborative effort with B. Low)

(Figure 4). A number of new techniques were also introduced in our lab. The most important was CAMELSPIN, conceived by Aksel A. Bothner-By.²⁷ In connection with the observation of high-field orientation effects,²⁸ we developed precise measurements of very small and poorly resolved splittings by cosine division or by tailored resolution enhancement,²⁹ and precise measurement of large (^{13}C , ^1H) splittings by cross correlation of spectral segments. In 1984, in collaboration with C. A. Fyfe, we recorded the first ^{29}Si and ^{27}Al MAS spectra of zeolites at 14 T.³⁰ In 1986 we increased the operating frequency to 620 MHz and actually observed slightly better homogeneity. In the same year Bruker Instruments demonstrated the first commercial 600 MHz spectrometer with a persistent Oxford Instruments magnet. In 1991 we recorded a few spectra at 630 MHz and we think that we could go up to 650 MHz, but the risk of a possible damaging quench makes such a move questionable.

During the 15 years of operation we had only two accidents where we were forced to de-energize the magnet. Both happened during the first years, before we put a fence around our magnet. In one of them a technician offered the magnet a pair of cutting pliers in his rear pocket. The pliers stopped close to the center of the bore after piercing a 10-mm Teflon plate.

THE 900 MHz PROJECT

While the 620 MHz system operation was underway, we started to plan the next stage. Bert Wang from Lawrence Livermore National Laboratory (LLNL) had just started his private enterprise and he was willing to try to go up with the field to 21 T. We submitted a joint proposal to NIH in 1984, but it was turned down. In 1985 we tried again with IGC (Dennis

Markiewicz) and with LLNL (John Miller, Don Slack), and in 1987 the first phase of a 900 MHz system development was under way. The goal was to develop superconducting wire for a 21.15 T magnet which would operate at 1.8 K, and to perform a test on a scaled-down coil. If successful, we would build the final version of the magnet and electronics during the second phase. The wire development called for doping the Nb_3Sn multifilament wire with tantalum, and it ran into a series of difficulties. The test on the small coil was delayed, but thanks to intensive cooperation of IGC and LLNL the coil was finally built in 1990 and in September we were able to perform the test successfully. The coil was placed into a 1.8 K Dewar inside a huge 10-T superconducting magnet at LLNL, and was then energized. The test was monitored from a big control room and the atmosphere was similar to that of a rocket launch; everybody was quite tense and there were congratulations after the final quench. We reached a maximum field of 20.4 T as planned³¹ and the remaining 0.6 T would be achieved by a small reduction of the operating current density.

Unfortunately we were not able to obtain funding for the second phase, i.e., for the building of the whole 900 MHz system. It can be expected that other groups in the future will try to move up to an operating frequency of 900 or even 1000 MHz. In the meantime, Oxford Instruments and Bruker Instruments have both announced persistent magnets for 750 MHz. The proton spectra displayed at the 34th ENC (1993) have confirmed again that there is no substitute for NMR at high field and that the upper limit in operating frequency is still far away.

Biographical Sketch

J. Dadok. b 1926. M.S., 1951, Technical University Brno, Czechoslovakia, Ph.D. 1963, Institute for Scientific Instruments of the Czechoslovak Academy of Sciences, Brno. Headed a group responsible for the development of high-resolution NMR spectrometers in Czechoslovakia (1957–67). Involved in design and operation of high-field NMR spectrometers with superconducting magnets in collaboration with A. A. Bothner-By at Carnegie Mellon University in Pittsburgh, PA, 1967–present. Faculty member in Chemistry Department, 1972–present. Research specialties: shimming of superconducting magnets and lineshape analysis, stabilization of nonpersistent superconducting magnets for very high fields, rf probe design, processing of NMR signals by computer. Proposed a new technique for the efficient accumulation of NMR spectra known as rapid scan correlation NMR spectroscopy.

Diehl, Peter: NMR at the Physics Department of the University of Basel, Switzerland (1949–96)

Peter Diehl

Physics Department, University of Basel, Switzerland

When, in autumn 1950, I arrived as a young student at the University of Basel, NMR was already five years old, being used mainly by physicists as a method for measuring unknown spins and magnetic moments of nuclei, although the nitrogen chemical shift had already been observed by Proctor and Yu.¹ In Basel, two people, Alder and Halbach, had just finished the construction of a low-resolution NMR spectrometer and were busy looking for the signals of the ^{175}Lu and ^{176}Lu nuclei as well as for the spin of ^{53}Cr . Alder had previously been working for a year with Bloch's research group at Stanford. In 1953 I had my first contact with NMR, helping to measure the effects of low-frequency field modulation on the signal shape. By then the chemical shift as well as spin–spin coupling were well-established phenomena, and when I started my thesis in 1954 I suggested entry into the field of high-resolution NMR to the director of the Physics Department. He was not very enthusiastic because Alder and Halbach had in the meantime left the Department. His decision was that either I should do research in nuclear physics as all my colleagues, or that as part of my thesis I should construct the spectrometer singlehandedly. Luckily I was naive enough to accept the condition, and started first slowly to improve the magnet field homogeneity winding coils and also fixing thin nickel foils on the pole shoes. As a byproduct, and because the linewidth was still considerable, I studied the quadrupole relaxation of ^{35}Cl in liquids and published my first research paper on this subject in 1956.²

The construction of the spectrometer was not easy, particularly because I had to use available electronic parts, e.g. the crystals for the transmitter and for the intermediate frequency amplifier were US army surplus material. The frequencies did not fit so that I had to adjust them by polishing the crystals manually, measuring the polishing time with a stop watch, because I had tested how many kilocycles of frequency increase could be 'rubbed off' per minute.

In 1955, when Bloch was Director General of CERN at Geneva, I visited his research group. Arnold and Anderson showed me their permanent magnet spectrometer system, which having been shipped from Stanford to Geneva never again reached its earlier resolution. They introduced me to the idea of spinning the sample, showing me a large-scale model of a rotating sample tube containing water and aluminum powder.

When the construction of the spectrometer electronics was finished, the magnet was still of insufficient quality for high resolution. It was then decided to buy a Varian magnet and combine it with the home-built 34.2 MHz proton frequency spectrometer.

I vividly remember the moment in 1956 when I first ran the whole system. I had filled the sample tube with wine, of

which I had found a few bottles hidden and left below the wooden floor which had to be removed in order to construct the concrete magnet base which was sitting directly on the underlying ground. To my great surprise I immediately saw the water line as well as the famous ethyl alcohol peaks. The time stability of the magnet was still poor, however, and spectra had to be registered either on a wax-paper Sanborn fast recorder or had to be photographed from the oscilloscope screen.

I immediately started to study the influence of hydrogen bonding on the hydroxyl proton shift with my spectrometer³ and because the shifts were larger and more easily measured I looked at the ^{19}F resonance of BF_3 complex formation with water and organic molecules. This led me to analyze spectra affected by chemical exchange. The results were published as my thesis in 1958.⁴ During the period of my thesis we had visitors who stayed in Basel for a year, Proctor and Ogg, who brought considerable NMR experience with them and certainly enriched my NMR knowledge.

After my doctorate I remained at the Physics Department, although what I did was at least halfway between physics and chemistry. The financing of physics research was easier, however, because in these early years the title 'nuclear magnetic resonance' opened the door to funds for nuclear research.

My thesis had convinced the Director of the Physics Department, as well as some physical chemists active in the local chemical industry, that NMR could be used to solve chemical problems. Consequently, in 1958 money was provided to add a Varian spectrometer to the existing Varian magnet to be run at 56.4 MHz for fluorine and protons.

Using this spectrometer to look at the spectra of substituted benzenes, I was fascinated by the drastic solvent effects, particularly those of benzene; i.e., ASIS.⁵ However, precise measurement was impossible, because analysis programs only became operative a few years later.

In 1960 I had a chance to visit the NMR research groups of Richards at Oxford for a few months, where I also met Buckingham, and of Pople at the National Physical Laboratory at Teddington. At Oxford I found a rich collection of *meta*- and *para*-disubstituted benzenes which had earlier been used for IR spectroscopy and which I now reused in order to study the additivity of substituent⁶ and solvent effects⁷ on the proton shifts. There was also a computer program available for calculating the spectra. So I applied the substituent effects to the prediction of the fluorobenzene spectrum. I spent two months waiting in the 'queue' to use the computer, but the resulting spectrum was disappointingly different from that observed. At Teddington, where I met Abraham, Freeman, and Schäfer, I was fascinated by an idea which Pople had used to simplify the description of a particular spectrum, and was able to prove that the same idea could be generalized for all spectra containing at least one group of weakly coupled nuclei.⁸ This was the beginning of subspectral analysis.⁹

Back in Basel I was contacted by a group of organic chemists who were interested in ^{17}O NMR which had already been shown to be feasible. Together with a student, I started working in this field and we soon published the ^{17}O shifts of over 100 compounds.¹⁰

In 1962 I had a chance to visit the USA for the first time, being invited by the American Chemical Society to a meeting on high-resolution NMR spectroscopy at Boulder, CO. I particularly remember the evenings when, sitting at a round

table drinking large quantities of low alcohol content beer, I had a chance for fascinating NMR discussions with Pople, Schneider, Bernstein, Dailey, Sheppard, Becker, Lustig, and many others.

The probehead which we had bought for running ^{17}O spectra induced me to initiate the field of high-resolution ^2D spectroscopy¹¹ because the Larmor frequencies of the two nuclei are quite close. In our first publication we discussed all the various aspects of the method, i.e. sensitivity, chemical shifts, simplification of spectral analysis, quadrupole relaxation, dipole relaxation by paramagnetic ions, proton decoupling from deuterons by paramagnetic relaxation difference, solvent and isotope effects, the study of selective solvation, as well as kinetic studies.

In 1964 I had another chance to go abroad for a few months in order to cooperate with the research group of Bernstein at the National Research Council, Ottawa. There I applied my method of subspectral analysis to the *sym*-trifluorobenzene molecule whose spectrum had resisted analysis for over a year.¹² In general, subspectral analysis kept me busy until 1967.

Since 1963 I had heard and read about the NMR of molecules oriented in nematic solvents. In addition, I had had the possibility of discussing the method with Saupe in Freiburg and Englert who had taken a job with a pharmaceutical company in Basel. Although the spectroscopy looked rather complex and had been applied almost exclusively to molecules of high symmetry, I entered the field in 1968 together with Khetrapal who had come to Basel as a postdoctoral fellow. Our work advanced rapidly and we were able to publish approximately 1 paper per month on all aspects of this new spectroscopy. We discussed the dependence of the spectra on temperature, concentration, and spinning speed of the sample,¹³ and the use of direct and moment methods for their analysis. We analyzed spectra of molecules with low symmetry, detected isotope effects on the molecular orientation, and measured quadrupole coupling constants. We wrote about the existence of the deceptive simplicity in spectra of oriented molecules and, finally, used an electric field to rotate the liquid crystal optic axis in the magnetic field.¹⁴ At that time we were 'famous' in the Physics Department for our permanent 'smell' of liquid crystals and for our yellow hands. Practically all the available liquid crystals at that time had a yellow color and had to be subjected to considerable heat treatment to become isotropic and dissolve the solute. Heating had to be undertaken in 5-mm glass tubes and usually the samples boiled over.

Our 14th paper on the NMR of oriented molecules was an article which later became a Citation Classic¹⁵. It was published in the series 'NMR, Basic Principles and Progress' (by Springer Verlag), which Fluck, Kosfeld, and I had started in 1969 and which has grown to about 30 volumes in the meantime.

I should not forget to mention that in the 1960s and 1970s the annual Colloquia on NMR Spectroscopy organized in Aachen by Kosfeld, as well as the Experimental NMR Conferences at Pittsburgh, where I met Shapiro, Bothner-By, and Castellano, were very important for the permanent exchange of ideas with other NMR research groups.

In 1968 we modified the LAOCOON program so that it could be applied to spectra of oriented molecules,¹⁶ and in 1971 we demonstrated that the NMR of oriented molecules can

be used to study intramolecular motion and barrier heights.¹⁷ The latter paper has been cited over 170 times during the last 20 years.

In 1974, together with Sykora and Vogt, I began to look into the possibility of analyzing spectra automatically by computer. This idea had fascinated me for a long time, especially having experienced together with Burnell the rather tedious work of assigning about 600 transitions in the spectrum of *o*-xylene in order to find out whether the two methyl groups moved in geared motion.¹⁸ We investigated two related strategies. In one we compared the least-squares fit with the problem of finding the deepest crater in the deepest valley of the moon by rolling a sphere on the lunar surface. Obviously, to avoid getting caught in the thousands of relative minima these had to be filled with sand, i.e. the sharp transitions had to be broadened artificially. This basic approach was later on taken up and realized by Binsch.¹⁹ In the second strategy we started from the idea that for automatic analysis a spectrum had to be transformed into a set of mutually independent figures, each describing a specific property of the spectrum. Obviously, the only possible such set had to be integral transforms of the spectrum. After many trials we arrived at the conclusion that Fourier transforms were ideal. In the iterative automatic least-squares fit an increasing number of such transforms were used in combination with a few spectral moments for centering the system at the correct position. In this way the program worked like an analysis by hand, fitting at first the rough features of the spectrum and subsequently the finer details. Although it took a whole year to get our program²⁰ working, we enjoyed this period of hard work very much and amused ourselves by testing the 'stupid' skill of the program which was even able to fit a cross section through the Swiss Alps as a four-spin system.

In 1976 we introduced the study of ^{13}C and ^{15}N satellites in proton spectra of oriented molecules in order to determine not only proton but also carbon and nitrogen positions.²¹

In 1977 we obtained our first Fourier transform 90 MHz spectrometer from Spectrospin-Bruker.

Our next achievement in 1979 was a program [VIBR] for the correction of direct couplings for vibrational motion. These corrections turned out to be particularly important for the determination of C–H bond lengths which, when compared with different methods, had usually turned out to be too long in the spectra of oriented molecules.²²

There was still one unsolved problem in this field: the apparent structures of molecules were solvent dependent. We attributed this dependence to a correlation between the structure and orientation of the dissolved molecules. The same process had been suggested earlier to explain the direct couplings observed in tetrahedral molecules where the static coupling must be zero.

Already in 1974 I had tried a correlation model in which the molecule existed in two complexed forms with slightly different structures, and showed that the true deformation is usually amplified in the measured spectrum to an unusually large extent.²³ In a more complex approach, in 1975 we interpreted the difference between the observed and vibration corrected structure of benzene and the theoretical hexagon as being due to the continuous deformation of the molecule as a function of its angle of orientation with respect to the liquid crystal director.²⁴ Finally, with the help of Lounila, we developed a generally valid deformation model²⁵ and in 1986 constructed the program MASTER.²⁶ This is able to

derive the solvent-independent molecular geometry, as well as the interaction tensors between the individual molecular bonds and the anisotropic liquid crystal potential which are responsible for the deformation and degrees of order of the solute simultaneously. This actually brought the method of structure determination of oriented molecules into a final form.

In 1987 we obtained a Bruker superconductive 250 MHz spectrometer. During a visit to the Indian Institute of Science in Bangalore in 1989 I started, in cooperation with Khetrapal, to study the interactions of ions with molecules dissolved in liquid crystal solvents.²⁷ We also tried to deduce the complex geometry from the observed changes in the degrees of order, i.e. from changes in the interaction tensor.²⁸

It was again molecular deformation by the liquid crystal which 'pushed' me into an entirely different field of research which at present still keeps us busy. I started with the idea that because tetrahedral molecules are deformed in the liquid crystal, an even 'simpler' charge cloud should also be deformed. The cloud was chosen to be the noble gas ^{131}Xe and the deformation was measured via the quadrupole splitting of the Xe signal.²⁹ As a by-product of this study, performed in cooperation with Jokisaari and his research group from Oulu, Finland, we noticed the extreme sensitivity of the Xe shift which clearly indicated phase transitions as well as the nature of the liquid crystal phase.³⁰ This, in turn, led to the question of shift-sensitivity and the solvent effects of noble gases in general i.e. Xe, Kr, Ne and, finally, He. We found a surprising linear relationship between the solvent effects of all the noble gases.³¹

Finally, as a typical example of how research often works by looking for something but finding something else which may be even much more interesting, I mention our latest results on ^3He which, by coincidence, we observed not only as a signal from the sample volume but also as a separate signal from the gas diffusing through the glass wall.³² This means that the well-known shift-sensitive but relatively large probe-nucleus ^{129}Xe , which is used for characterizing the solid state properties of, for example, clathrates and zeolites, has a considerably smaller 'brother', ^3He , which is not shift-sensitive but can contribute information via its relaxation behavior and as a probe for measuring local magnetic fields.

NMR studies in the Physics Department of the University of Basel are planned to end in 1996 when I will go on pension. The Department will at last get rid of a permanent 'foreign body' which for the physicists was too chemically oriented, for the chemists too physical, and for physical chemists located in the wrong department. In contrast, I believe that this 'outlaw position' made it possible really to enjoy the freedom of research and I hope that some of our pioneering contributions will permanently survive in this beautiful and endlessly fascinating spectroscopy.

Research specialties: ^{17}O spectroscopy, spectral analysis, ^2D spectroscopy, oriented molecules in liquid crystals, noble gas NMR.

Doddrell, David M.: An Historical Perspective of Research Based Upon Misguided Advice

David M. Doddrell

University of Queensland, Brisbane, Australia

I have often wondered just how a scientific discovery is made; after 27 years as an active researcher I still don't know. Our understanding of the cognitive processes in the brain are so poor that little solitude can, in my view, be obtained by turning to the neuropsychologists to provide a satisfactory explanation. I have always been surprised at the important contribution of serendipity, along with the added ingredient of being at the right place at the right time.

I began research in magnetic resonance in 1967; I had been advised then not to enter the field as it had no future! This is about as good advice as I gave in a lecture at Caltech in 1970 when I stated that I thought that Fourier transform methods in NMR did not have much promise. Predoctoral student days at Indiana University in 1967–70 were exciting times; Art Clouse, an electronics engineer retired from the US Navy, taught me how to set up ^{13}C NMR with ^1H decoupling. An old Navy reject frequency source (frequency variation about 100 Hz min^{-1}) provided the proton channel with noise decoupling induced via a double-balanced mixer; off-resonance noise decoupling to count nonprotonated carbons was the outcome of this research,¹ the product of having such an unstable frequency source. Of course, Jack Roberts' group at Caltech had already done these experiments² and more, but they had a frequency synthesizer! All this work was done with field or frequency modulation methods not FT techniques. In 1971, I was lucky to be Adam Allerhand's first postdoc. He and Clouse had built an FT spectrometer for ^{13}C NMR and my task was to help measure and understand ^{13}C T_1 and NOE values. Our fear was that they may be uselessly long (we guessed tens of seconds for protonated carbons—thus my comment in 1970 about FT methods). Of course history proved that we were up to a factor of 100 too long in our guess; the major result of this work was that we had developed a simple method of studying solution molecular dynamics which is still in use today.³ I also consequently understood Solomon's 1955 paper on dipolar relaxation.⁴

In 1979, Morris gave me a copy of his paper⁵ with Freeman on INEPT. I was in Canada at the time. On returning to Australia Jim Field and I implemented this pulse sequence; Field built the hardware and I 'played'. It was clear that not only did one get the polarization transfer enhancement as Freeman and Morris claimed, but by changing the appropriate delays CH , CH_2 and CH_3 proton-decoupled carbon signals could be easily distinguished via their phase variation.⁶ Overnight, off-resonance decoupling methods were made obsolete. We, at least here in our group when I was at Griffith University, all found the Freeman/Morris explanation of INEPT unsatisfying. David Pegg, a theoretical physicist, came up with the concept of spins rotating in the doubly-rotating frame as a general approach to multipulse methods

(we had unwittingly invented another name for multiple quantum effects) and complex vector diagrams were the order of the day.⁷ These diagrams did allow Robin Bendall to predict the EPT pulse sequence⁸ that was designed to give a proton-decoupled ^{13}C CH subspectrum exclusively. It did, but while pulse programming it I made an error in setting the 'multiple quantum' proton read pulse angle (we did not call it that in 1981) and the DEPT pulse sequence was born.⁹ The variation of signal phase dependent on the proton multiple quantum read pulse angle was classic serendipity; we knew what we had done but no simple vector diagram could ever have predicted the result. The theory at the time had to be cast in terms of computing the time evolution of the spin system during the pulse sequence,¹⁰ as with the vector description, not a particularly useful predictive approach to multipulse NMR. In 1982, while on study leave at Cambridge, Ruth Lynden-Bell taught me about product operator algebra.¹¹ Of course, Packer¹² and Sørensen et al.¹³ published different constructions of this algebra and it could be argued that the development of product operator methods was one of the most important advances in NMR in the 1980s. Although DEPT was serendipitous in its genesis but simply understood retrospectively using operator methods, not so with the POMMIE pulse sequence. Mark Bulsing and I reasoned that if polarization transfer could be induced via a multiple quantum read pulse of parametric angle (DEPT) then a 90° pulse with parametric phase must also work. The pulse sequence we published is correct¹⁴ but the original theory as published is wrong; this was subsequently corrected in a later paper.¹⁵

My education in NMR took a new tack in 1985. I started to learn about pulsed field gradients: we had bought a horizontal magnet system. Whereas the introduction of operator algebra made the understanding of solution state multipulse methods straightforward, pulsed field gradients seemed to defy logic. They induce that curse of NMR spectroscopists, eddy currents. Oh, the ideas were simple, but the 'in practice' implementation of a field gradient pulse sequence in a magnet is a different matter. Even today with shielded gradients there is still a degree of art in setting preemphasis, cross preemphasis, and B_0 correction. Sometimes the trimming procedure of a gradient sequence appears to be illogical but achieves the best results. In 1985, Bill Brooks and I started to 'play' with shaped rf pulses; for a sinc pulse we noted the 'well known' linear phase roll with frequency offset and that it could be refocused with a hard 180° pulse; the SPACE image-guided volume selection method was born.¹⁶ The short T_2 encoding of this method allows the observation of the signal from many brain metabolites with better sensitivity than using other volume-selection 'echo' methods; the human spectroscopic applicability of the SPACE method remains problematical, however. Of course, if we had read Fernbach and Proctor's 1955 paper¹⁷ on a phase memory device, SPACE would have been obvious; so might have been slice selection in magnetic resonance imaging.

It was of course natural to attempt 2D NMR in vivo; we had noted that gradients were very effective for water suppression and naturally incorporated them into our volume-selected 2D sequence. We were amazed that we could induce ω_1 quadrature selection without phase cycling. Hurd published similar results¹⁸ for solution state NMR but Freeman had published a gradient enhanced COSY in 1985.¹⁹ But why did gradients induce ω_1 quadrature detection? I simply did

not believe the results and I made Stuart Crozier repeat the experiment using a 'read' gradient of different polarity. Sure enough N or P type selection could be induced simply by changing the gradient polarity.²⁰ We incorporated gradients into the product operator description of the COSY sequence and the results were readily explainable. While in France in 1990 I did some algebra in my head and proposed a heteronuclear gradient-enhanced experiment.²¹ It worked, but not in the way that I had guessed. It took Ian Brereton and me a number of months to sort out that mess; moral — don't take everything for granted, but do guess.

I often reflect on the original advice given in 1967 that NMR had no future. Its inaccuracy has taught me to be guarded in counseling my own students and I look back over the past 27 years and wonder what I would have done if I had listened in 1967. The answer of course is indeterminable.

One last comment. I am often asked the unfair question, 'Except for the discovery of the technique, what was the most important conceptual advance in NMR spectroscopy?' My answer is that Erwin Hahn has a lot to answer for.

Doskočilová, Danica & Schneider, Bohdan: Development of Magic Angle Rotation for the Narrowing of Proton NMR Lines in Organic Materials

Danica Doskočilová & Bohdan Schneider

Academy of Sciences of the Czech Republic, Prague, Czech Republic

In introductions to scientific papers, the state of the art is invariably described together with clearly defined aims. To show how things sometimes actually work, let us tell the story of our development of the magic angle spinning method for applications in proton NMR.

At Christmas time of 1962 we were lucky to install the first commercial NMR spectrometer (JEOL JNM-3-60) in the then Czechoslovakia in the Spectroscopy Department of our institute which was engaged in studies of synthetic polymers. It was equipped both for classical ^1H broadline measurements and for ^1H high-resolution work in liquids. It was without lock, of course, but it had easy switching from broadline to high-resolution regimes and a very good variable temperature outfit.

By that time the basis of CW ^1H high-resolution work in liquids had already been conveniently summarized in the classical book by Pople, Schneider, and Bernstein, and we quickly proceeded to apply it to structural studies of polymers and especially of their model compounds. The weird observation that the PVC dimer model compound—*meso*-2,4-dichloropentane—a molecule with only a mirror plane of symmetry, exhibited equal vicinal coupling constants, $J_{\text{AX}} = J_{\text{BX}}$, in its ABX_2 spectral pattern led us to realize the existence of rapid conformational interconversions in polymer model compounds, and ultimately in the polymer molecules themselves. For some years subsequently we concentrated on a study of the conformational structure of polymer model compounds by a combination of vibrational and ^1H high-resolution NMR spectroscopy, thus establishing a basis for both experimental and theoretical studies of polymer conformation and configuration.

Nevertheless, it quickly became clear that our dear JNM-3-60 was becoming obsolete for high-resolution work in liquids. Moreover, many synthetic polymers do not dissolve in NMR solvents and, even when they do, for most practical purposes they are applied as solids and therefore should be studied as such. Looking around for a way to utilize the remaining excellent properties of our JNM-3-60, the imagination of one of us (B.S.) was caught by the 'magic' of rotational line narrowing (MAR), described by E. R. Andrew and I. J. Lowe in the late 1950s for some inorganic solids. According to theoretically versed physicists, the odds were against us for ^1H NMR work: in rigid samples the large dipolar broadening would require virtually inaccessible spinning speeds, whereas in samples with naturally narrowed NMR

signals (such as polymers) further line narrowing would be prevented by the existing internal motional frequencies. Nevertheless, we would not be dissuaded from our MAR gadget and actually our first turbine, machined directly from methacrylate glass and spun about a central wire, did give some kind of effect.

During a short visit to Professor Andrew in Nottingham in 1967, B.S. inspected his spinning mechanism with a lower conical bearing and discussed with him all contemporary views of the success (or failure in the case of ^1H) of MAR. Agreeing on the fact that a good theoretician should always find an explanation for a positive experiment, they parted as friends. Meanwhile in Prague, in collaboration with our electronics engineer Z. Růžička and the head of the Institute workshop J. Babka, by making use of the excellent skills of the workshop mechanics we built¹ within seven months an apparatus suitable for proton MAR NMR. The probe could be inclined continuously from 90° to 53° with respect to the magnetic field, and permitted direct transition from broadline to high-resolution measurement which was important in our preliminary experiments and attempts at theoretical interpretations. The nitrogen gas propelled turbines were suspended in two conical dynamic gas bearings and reached spinning speeds of up to 10 kHz when machined directly from a suitable solid polymer. We also developed² hollow glass turbines which could be spun up to 5 kHz for the measurement of liquids in suspensions or sorbed on powders. To achieve a field homogeneity necessary for high-resolution work at the sample site, the probe housing and gas jet construction were built from nonmagnetic materials. With our very limited conditions at that time, this was only possible thanks to the very profound knowledge and love of exotic materials of Z. Růžička, so that almost anything could be found in his garage (but no car!). At perfect magic angle setting, we could reach a resolution of 3 Hz. Within a short time the apparatus was also modified for operation at variable temperature.³ To this day, spinning assemblies of very similar type are used in all modern solid state high-resolution NMR spectrometers.

Already in our first communication on the subject,¹ most prospective applications of ^1H NMR line narrowing by magic angle rotation had been listed and the criterion for a positive line narrowing effect was stated in terms of the good old theory of Gutowsky and Pake:⁴ to obtain line narrowing by magic angle rotation at practically attainable spinning speeds, the static linewidth must be partially narrowed by internal motion which is anisotropic in space, with residual static dipolar interactions. The resulting residual linewidth in the MAR NMR spectrum is limited by the frequency of the internal motion which causes partial narrowing of the static spectrum. The applications included studies of the phase structure in solid polymers, motional frequencies of various proton groups in liquid crystalline polymer solutions, and the structure of swollen cross-linked polymer gels, the latter two applications thanks to the construction of the turbine allowing the measurement of more or less liquid samples.⁵ In later developments it was shown that by combining the information from MAR NMR spectra with static lineshape analysis, information could be obtained both on the dynamics of internal motions and on the degree of their spatial anisotropy.⁶

In this work, we were traveling a very lonely path. We made mistakes. We did not patent our apparatus abroad, only in Czechoslovakia, and even that at a rather late date (1971).

In the late 1970s, the advent of pulsed ^{13}C NMR was followed by an explosive interest in the magic angle spinning method (from then on called MAS), and its success quenched any interest in ^1H MAR. Having at that time no suitable ^{13}C NMR spectrometer we did not participate in that boom, though some of our previous experience was almost tacitly absorbed in it.

Doty, F. David: A Random Walk Toward High-Speed Sample Spinning

F. David Doty

Doty Scientific, Columbia, SC, USA

My introduction to ESR and NMR began under Charlie Poole¹ in the graduate Physics Department at the University of South Carolina. There I became rather well known throughout both the Physics and Chemistry Departments as being unafraid to walk into any instrumentation laboratory and start dismantling equipment. This brazen behavior was tolerated because I would put the instruments back together with improved gadgets I had made (usually without permission) in the machine shop and electronics laboratories.

One spring day in 1979, (Ellis, Paul D.: *Multinuclear MR Experiments, the Surrogate Probe Strategy, and Other Fun & Games*) came looking for me. He needed some kilowatt UHF transmitters and a high-speed sample spinner that really worked to perform his solid state NMR experiments. At the time I was more confident with the transmitters, being well versed in the witchcraft of microwave and rf from ESR and years of TV repair experience. But I had also been rebuilding automobile and tractor engines since early childhood and was keenly interested in turbomachinery—with visions of the Brayton cycle achieving 65% energy conversion efficiency dancing in my brain.

After completing the transmitters and struggling for a few months with the Andrew–Beams spinners, I came to the conclusion that the problems with low-frequency torsional modes (several hundred Hz) and frequent instabilities above 2 kHz could only be solved by going in the general direction that Lippmaa, Veeman, Pines, and others were going: double cylindrical air bearings (see *Solid State Probe Design*). Paul wanted to look at natural abundance ¹³C in surface-adsorbed species, so it was necessary to explore the use of high-strength ceramic rotors for improved filling factor (see *Probe Design and Construction*). We found operation at moderately high spinning speeds to be much more difficult than the early papers seemed to imply—at least with the higher density ceramic rotors. Catastrophic explosions from materials defects were common, so I became very experienced in the precision diamond grinding of hard ceramics. On more than one occasion I would work through the night in the machine shop (my wife Judy would sometimes relieve me at the lathe) so that the NMR experiments could continue the next day.

However, we could not blame all the crashes on ceramics defects, so it was necessary to do a more careful study of gas bearings and microturbines. It was encouraging to find calculated optimum bearing hole size and radial clearance reasonably close to experimentally determined optima, but that didn't make it any easier to eliminate systematic and statistical measurement errors or to reproduce the required dimensions.

Simple calculations eventually convinced us that we were often limited by the 'whirl instabilities' previously reported in gas bearings for dental drills. In church choir one Sunday, while half-dozing and half-listening to the resonant bass from

the organ, I worked out the increase in the conical whirl mode that could be expected simply by changing the turbine caps from Lippmaa's design (internally hollowed and filled with sample) to externally hollowed and empty.² The improvement proved to be greater than I had expected because of the additional beneficial effect on damping. After another year of constructive criticism from Ruth Inners, Paul Ellis, and J. B. Spitzmesser, my CP MAS probes appeared to be ready for a small commercial venture. In the spring of 1982, a physics colleague Bruce Sofge succeeded in convincing a wealthy friend to loan us approximately \$100 000. Judy, J. B., Bruce, and I started Doty Scientific, Inc. So it began.

In June 1986 at the EENC in Bad Aussee, Vagn Langer and Preben Dagaard upset the status quo by demonstrating the design they had developed for Varian with reproducible spinning at surface speeds above 70% of the speed of sound.³ Vagn was concerned that Varian would now put me out of business. I assured him that he needn't worry. The key difference was obvious upon casual inspection: the gas from Vagn's air bearings was allowed to exit axially in both directions, nearly doubling the area of the effective hydrostatic bearing and hence the radial stiffness. Indeed, this had been done by others before (so no problem with patents), but I wasn't doing it. A few months later, our high speed model emerged, and we were spinning routinely at 75% of the speed of sound. Vagn was relieved—Varian was dismayed.

My earlier work in energy conversion had introduced me to one of the great turbine engineers, David Gordon Wilson.⁴ In the spring of 1990, I called him up and asked him if he would be interested in collaborating on the development of an efficient microturbine. The ensuing relationship was one of the more rewarding of my business career. Most of the final supersonic spinner design details were worked out and communicated back to the plant by fax during the EENC in Veldhoven that May, and within weeks we had a manufacturable design approaching 90% of the speed of sound. A few months later we were achieving supersonic surface speeds and isentropic turbine efficiencies above 30% for 7-mm rotors (compared with 8% for our previous 7-mm microturbines), but scaling to smaller sizes proved to be nontrivial. The following summer while discussing with David the difficult resonances in our 5-mm spinner, we found time for a pleasant evening of singing old English madrigals with his wife around the grand piano in his living room in Cambridge. It was to take two more years and hundreds of failed experiments by my patient colleague Jerry Hacker during difficult recessionary times before we were to recognize several nonlinear scaling laws and the importance of the Bernoulli effects over the ends of the turbine blades and achieve routine spinning above 24 kHz with 3.5-mm rotors.

Dwek, Raymond A.: From Antibodies to Glycobiology

Raymond A. Dwek

University of Oxford, Oxford, UK

My career in magnetic resonance started in 1963 with Professor Sir Geoffrey Allen at Manchester University. Under his guidance, I completed my M.Sc. which dealt with using NMR to monitor keto–enol tautomerism. Learning that exciting things were happening at Oxford, in 1964 I joined the group of Sir Rex Richards, one of the pioneers of NMR in the UK. There, in 1966 I completed my D.Phil. My thesis topics involved nuclear electron double resonance. In Rex's lab, I obtained a very sound grounding of theoretical concepts and principles and also came into contact with many of the other leading figures in the NMR world. I stayed on for my postdoctoral studies with Rex Richards and was given an opportunity to develop several inorganic applications of NMR. These involved mainly studying the paramagnetic properties of transition metal ions and measuring the exchange rates of the molecules in the first coordination sphere.

A visit to the Institute For Exploratory Research at Fort Monmouth (1968), where I worked on other aspects of nuclear electron double resonance, convinced me that the use of NMR in the life sciences was really where the future growth was going to be. This was reinforced by a short visit to Professor Z. Luz at the Weizmann Institute in Israel the following summer. By this time, my interests in biochemical problems were known to Rex and shortly after my return to Oxford I was offered a position in the Biochemistry Department in Oxford under the Nobel Laureate, Rodney Porter.

Rex Richards and his group were still housed in the Physical Chemistry Laboratory in Oxford—I continued to use his equipment and collaborate with him. In the Biochemistry Department, I began a long collaboration with Professor George Radda and his group, in which we used paramagnetic probes and spin labels as reporter groups in phosphorylase A and B. At the same time, I was working on fluorinated sugars made by Paul Kent's group in conjunction with Professor R. J. P. Williams and one of his research students, A. V. Xavier. In 1971 I was elected to the newly formed Oxford Enzyme Group, which was under the chairmanship of Rex Richards, and developed a series of collaborations with many of the members mainly using techniques involving paramagnetic ions. These included I. O. Walker, A. Peacock, G. K. Radda, R. E. Richards, R. J. P. Williams, and my colleague Iain Campbell with whom I wrote *Biological Spectroscopy* in 1984. I collaborated with David Phillips and Louise Johnson on many structural aspects of substrates binding to lysozyme in solution and in this our joint research student Stephen Perkins played a major role.

By 1972 the advance in instrument design and particularly the use of Fourier transform spectroscopy had greatly improved the sensitivity of spectrometers. People were already talking about using NMR to solve the three dimensional structures of biologically important molecules, but there were also many other applications of NMR in biological systems. In 1973 I collected some of these together in my book—'Nuclear

Magnetic Resonance in Biochemistry: Application to Enzyme Systems'. The book was well reviewed, I remember one letter in particular from David Phillips in which he said that he 'admired the way in which you have brought out the immediate importance to biology of what might seem a somewhat esoteric development!'

In 1973, after what I thought was a particularly excellent seminar by one of my postdoctoral workers on phosphofructokinase, Professor Porter called me to his office to discuss the seminar. He pointed out that simply 'monitoring' conformational changes in large proteins using reporter groups might be interesting mechanistically, but without detailed 3D studies he did not consider it to be at the cutting edge. What was needed he said was a major assault on the antibody problem! With his guidance began an exciting and exhilarating time in which I switched my interests towards the antibody molecule. Professor David Givol from the Weizmann Institute came over and together we started what was to be a nine year collaboration studying antibody combining sites. In the early days, I thought that the problem was tremendously difficult. I prepared a series of feasibility studies for Rodney Porter in which I did not rate our chances highly. What made the combining site problem soluble was mainly that the addition of a hapten (a small molecule) to an antibody combining site only perturbed those resonances in and around the combining site. Difference spectroscopy then enabled us to obtain subspectra of the combining site. I had some wonderful colleagues in Oxford, and with them we actually solved the combining site of the myeloma protein MOPE 315 which bound dinitrophenyl haptens. In 1976, we published the structure of this binding site in *Nature* and it was gratifying in 1988 to find that somebody had finally crystallized it in David Phillips's laboratory and that the structure reported was very similar, if not identical, to that determined by NMR. Our approach to the antibody combining site had been to gamble in 1973 that the fold of all antibodies would essentially be conserved. We built our amino acid residues onto the fold and then refined the model using NMR data, spin label data, and a whole host of other complementary physical techniques. We observed very large ring current shifts of the hapten when it was in the combining site and this necessitated a recalibration of the Johnson–Bovey ring current tables. Our connections with our colleagues Louise Johnson and David Phillips enabled Steve Perkins to complete these studies and recalibrate the ring current tables based on the crystal structures of lysozyme.

My interest in paramagnetic ions had, of course, continued. With Dennis Burton in Sture Forsén's lab in Lund, I continued a collaboration on proton/deuteron relaxation enhancement. When Dennis Burton came to England to do his postdoctoral work in my laboratory, we continued to use a variety of nuclear magnetic resonance techniques as we turned our attention towards the Fc portion of the antibody molecule. This is the portion of the molecule that is concerned with the elimination functions of the antibody—once it has bound the antigen. Our interests widened and with the aid of Professor J. Novotny and colleagues, we predicted the Clq receptor site on the antibody Fc region on the basis of sequence conservation, accessibility, and other studies. It was, however, these interests in the effector functions of antibody, mediated by receptors binding to the Fc, that led to the question whether the conserved carbohydrate in the Fc domain IgG molecule played an important role. This led to the challenge of studying the

carbohydrate structures of antibodies and led me into the area of 'glycobiology'

Dybowski, Cecil: Bob Vaughan and Solid State NMR at Caltech in the 1970s

Cecil Dybowski

University of Delaware, Newark, DE, USA

The first time I met Bob Vaughan was in Chuck Wade's office at the University of Texas. Bob had given a seminar at Texas and I felt fortunate to have a few minutes to talk with him. It was late 1972 and I was finishing the work on my dissertation. While the bulk of my work had been watching flashes on an oscilloscope to measure T_1 values, one of Chuck's other students, John Howell, had built a pulse sequencer. We tried some multipulse sequences with our Magnion spectrometer, but it was obviously more difficult than I had at first thought. Here was the opportunity to talk with someone who had done this experiment. What a generous and open person he seemed to be in this first meeting—entirely open about his work and extremely interested in what we had been trying.

In February 1973, Bob called me because Won-Kyu Rhim had gotten a position at JPL. He asked me to come to Caltech as a postdoctoral fellow. What an opportunity!! I would be able to work on pulse sequences which was the thing to study at that time in NMR, following the seminal work in Waugh's group at MIT. By summer I was at Caltech, with both awe and trepidation.

At Caltech the experiments were done in an old Varian magnet Bob had gotten, I believe, from Roberts. Its vintage was indicated by a single-digit serial number. Averaging was limited by the time we could maintain its stability, at the most about 8 h. The PDP-8 computer was loaded from paper tape, and when loaded all except two bytes of computer memory were used. There was no storage outside computer memory, so one took a spectrum, transformed it, and plotted it. There could be no mistakes or the whole process had to be repeated.

Despite the modest setup, the laboratory was tremendously impressive. Perhaps the most significant facet of the lab was the elaborate care taken to produce uniform, controlled radiofrequency excitation. At Caltech at that time, the actual experiments were a minor part of the time one spent in the lab; most of the work was spectrometer setup. Bob was a master of the art, from rudimentary settings to the most subtle details. For example, he could lean on the spectrometer console and the tuning would change, and he knew why and by how much it would change. This attention to detail was the key to being able to do experiments few others could do.

Bob had been a student of Harry Drickhamer at Illinois and, to my knowledge, did not do significant amounts of work in NMR spectroscopy as a graduate student. I attribute Bob's success not just to his rather gigantic intellect, but also to the fact that he came to NMR experiments with no preconceived notions about them. Rather, he went about them in an extremely logical way with no shortcuts or presumptions about the way things 'should' operate. Every detail mattered

to him and every adjustment was made while mimicking spectrometer operation during the experiment.

I met Drickhamer once when he visited Bob at Caltech. I realized immediately many of Bob's traits, including his global view of problems and his detailed approach to experimentation, were direct spinoffs of Drickhamer's approach to scientific problems.

As a postdoctoral fellow at JPL, Vaughan was tremendously influenced by Dan Elleman. He, Rhim, and Elleman had collaborated on multipulse NMR experiments before I arrived at his lab, and I could feel the great respect Bob held for Elleman. It seemed to me that he, Elleman, and Rhim formed an excellent team, each with unique strengths to contribute to the overall effort.

The year before I arrived, Bernie Gerstein was a visiting professor in Bob's lab. When I arrived, he was finishing the sabbatical there and was preparing to return to Iowa State, where later he would independently make major contributions to solid state NMR such as CRAMPS. Bernie and I were office mates for a month and became close friends in a way few do—a friendship that has endured for 20 years. I continue to be amazed that such a strong bond was forged in such a short time, but I am happy to be the beneficiary of its strength.

The years I spent at Caltech saw a dramatic change in the Vaughan laboratory. The number and variety of students increased from two (Schreiber and Lau) to something like a half dozen, from chemistry, chemical engineering and physics. This diversity produced a lively atmosphere I have found nowhere else. The strengths of each person seemed to be enhanced by others in the group, each working independently, yet relying on the others for philosophical, and practical, support. The result was a way of learning independently about one's project by interacting with others.

In addition to the graduate students, postdoctoral fellows, and faculty, various distinguished visitors would frequently visit Caltech. David Grant spent a year as a Sherman Fairchild Scholar. During that year, he actively participated in the Vaughan group seminars and added to the lively debate in those multihour marathons. I also vividly remember Ed Stejskal's talk on magic angle spinning and Hans Spiess's visit to Caltech. After we had had dinner, I remember Bob telling me 'There's a guy to watch. He is really good'. In addition to his keen understanding of the technology and science, Bob obviously had the ability to recognize talent in others and admit it freely.

The graduate and undergraduate students were excellent. For example, we were putting together the first system in a superconducting magnet after I arrived. Doug Carson had the job of working on the new PDP computer to make it control the experiment, and I remember how he struggled with its idiosyncracies. My part was the rf. It was exceptionally difficult to adjust the probe tuning at first, since we had only a vector impedance meter that went to 108 MHz, and the probe was to be tuned at 200 MHz. I remember how relieved I was with the arrival of a new vector voltmeter, for I could then adjust the tuning and measure the result easily.

After I finally got the probe adjusted to my satisfaction, I began to use the spectrometer to search for the proton resonance. Of course, I saw no signal where the Bruker engineer had when he brought the magnet up with his probe weeks earlier. I worked for a week doing various things, and still saw nothing. Then one of the really fine students,

Mike Stoll, joined in the search. Each day we would start at the frequency where the proton signal had been found in the Bruker probe and lower the frequency, reasoning that the magnet might have a slightly lower field than when first brought up (why? I don't know). Mike, on one of the many days, noticed a tiny blip in the spectrum which he concluded was the signal folded over many times. I wouldn't believe it. He pulled out paper, pencil, and calculator and calculated the expected attenuation by folding. With these calculations in hand, he made the bold prediction that the actual resonance was at higher frequency. To placate him, I moved the frequency up, and the signal increased by just the amount he calculated. We continued this process and, in short order, had a gigantic signal. Apparently because of slight differences in the probe I had built and the Bruker probe, the resonance was actually at *higher frequency* in our probe. Thanks to Stoll's faith in the laws of physics, we finally found the water signal.

Having a superconducting magnet meant more than just a second spectrometer; the increased sensitivity and stability gave us a real opportunity to investigate adsorbed phases—Bob's passion. Bob had been unjustly criticized by some for not moving more swiftly toward the study of adsorbed materials, but it was obvious to us that one had to deal with the development of technology first; the applications came later. After I left the lab, students like Mike Duncan would develop the study of surface species with NMR spectroscopy, although Schreiber had done some elegant preliminary studies in the old Varian magnet on the proton resonance of the surface hydroxyls of silica-aluminas.

Bob had another passion that surfaced at morning coffee. He and I would be at Chandler Dining Hall for coffee at 8 a.m., despite the fact that we had worked until 12 midnight or 1 a.m. the night before. We'd talk about lots of things dealing with NMR spectroscopy. I had decided to look at relaxation under multipulse sequences, and that was always among the topics we started out on as I added cream and sugar to the coffee.

During these daily routines, we'd often be joined by George Gavalas and John Seinfeld. NMR ceased (under duress) to be the topic of conversation on those occasions. It was at those times that Bob's other passion, money and the economy, appeared. He had very definite ideas about the subject, on which he would gladly speak whenever there was a willing audience. It was in these moments that you could see that Bob was a dyed-in-the-wool *laissez faire* capitalist! Not too surprising for a boy from Macalester, Oklahoma!

Speaking of Oklahoma, I had the worst run of luck during my time at Caltech. Being a graduate of the University of Oklahoma, Bob was always ready to place a gentleman's bet on the outcome of the Texas–Oklahoma football game. Fortunately for Bob (and unfortunately for me), those were the halcyon days of Oklahoma football. Needless to say, I had to buy the beer every October while I was at Caltech, thanks to the Texas and Oklahoma football teams.

There were many other incidents that showed the uniqueness of the time and place that was Vaughan's lab in the early 1970s—a place that was stimulating, innovative, and humane, not pretentious or overblown in its claims. However, ultimately my tenure there had to end, and I moved on to Delaware. I was very fortunate, because the DuPont Company had the wisdom to make Bob a consultant, and I saw him frequently after

I moved to Delaware. We spent many evenings in pleasant conversation (after he had spent a full day at DuPont!) talking about the latest experiment one of us was trying.

When I came to Caltech, Vaughan's lab was a small operation concentrating on the technology of one NMR experiment. During my time there, I saw a transformation that really came to fruition after I had moved to Delaware. Those people not only expanded the technology of NMR in many ways, they were engaged in an ever-widening array of unique NMR experiments. Indeed, they really brought to fruition the studies I thought I'd come to Caltech to pursue, but never really was able to 'get into'—NMR of adsorbed materials.

I talked to Bob last about a week before his death, when he was again at DuPont. We discussed the upcoming meeting in Menton, France, to which we were both going. Bob seemed at ease because many of his problems were behind him and, both personally and professionally, his star was rising quickly. We agreed to meet in Paris before continuing to the Riviera.

The day of his death I called his office to talk about meeting in Paris before proceeding to Nice. His secretary, Sharon Vigario, told me Bob was in Chicago, that he would be home that evening, and she would have him call me the next morning. It happened that on the TV news that evening, when they talked about the air disaster on the Chicago to Los Angeles flight, a list of victims' names was put on the screen. I was relieved not to find his name there. After all, there were lots of flights from Chicago to Los Angeles.

As it happened, Bob pulled his usual trick of booking a late flight, returning on standby on an earlier one. He was on the flight! Even after 15 years, I still see in my mind the newspaper photo of the hapless airliner, and I realize how unsympathetic and cold death is.

What was the legacy of Vaughan's brief, illustrious career? The scientific papers speak clearly of intellect and curiosity and the scientific innovation that Vaughan engendered in others around him. They run the gamut, from highly theoretical projects, such as the proof of the spinor properties of nuclei, to very applied, such as studies of the nature of various catalytic surfaces.

I shall always consider him one of the three great scientific mentors in my life. He taught me science, patience, and kindness. His lasting legacy is really a single generation of scientists and engineers who have contributed to the improvement of NMR spectroscopy, science and the world through their own work and that of their students. I often wonder how many subsequent generations there would have been if only he had missed that plane from Chicago, and what the 1980s and 1990s would have been like at Caltech had he lived on.

Ellis, Paul D.: Multinuclear MR Experiments, the Surrogate Probe Strategy, and Other Fun & Games

Paul D. Ellis

Battelle Pacific Northwest Laboratories, Richland, WA, USA

I am not old enough to do this, but given the nature of this Encyclopedia, I feel it is important to be able to recognize the colleagues that I have had the privilege to work with over the years during my tenure at the University of South Carolina (USC). I received my Ph.D. in 1970 at the University of California at Davis working with Professor Gary Maciel. I left Davis to go to USC just before Gary moved from Davis to Colorado State University in Fort Collins Colorado. Before I joined the faculty at USC Gary gave me some sage advice. He basically warned me that ^{13}C NMR was becoming too easy and hence popular (thanks to groups headed by Jake Stothers, David Grant, Gary's, and Jack Roberts) and it was going to be easy to get 'lost' given all of those efforts. Basically, he was pointing me to the remainder of the Periodic Table. A lesson I was not to forget. I left USC in early 1993 to move to Battelle's Pacific Northwest Laboratory. Here we are setting up an ultra high frequency (UHF) magnetic resonance lab for solids and liquids, e.g. a spectrometer based upon a 23 T magnet. My group is part of a larger effort in Environmental Molecular Sciences. The main effort of the laboratory (EMSL) is to provide molecular level understanding to the complex environmental problems which plague the world today. However, the main thrust of this note will be a summary of some of the early efforts to get Fourier transform multinuclear MR experiments going and the application of that method to metal sites in metalloproteins.

In the 1960s and early 1970s it was common for manufacturers of NMR spectrometers to build the spectrometer around specific nuclei rather than being broadbanded. Hence, if you purchased your spectrometer with ^1H , ^{13}C , and ^{31}P observe capabilities you would get three transmitters, three local oscillators, three preamps and, depending upon the manufacturer, three probes. It was a great marketing tool designed to bring in a gazillion dollars per spectrometer but a poor way to do science. This picture started to change when Dan Traficante¹ learned how to 'fake' a spectrometer into thinking it was performing a ^{13}C NMR experiment, when it was really looking at ^{29}Si . Basically what was involved was stepping up (or down) the transmitter frequency to excite the nucleus in question, utilizing a properly tuned probe, then stepping the transmitter down (or up) to detect the signal. Dan used a Bruker HFX-90 spectrometer for these modifications. Our group was using a Varian XL-100. Working with Charlie Peters of Varian Associates and Harold Walsh from the USC Chemistry support staff, we² put together a prototype of what would later become known as Varian's 'Gyrocode Observe Option', the first commercially available multinuclear observe accessory. These modifications provided a basis for us to perform NMR experiments on a wide variety of inorganic and bioinorganic systems. Utilizing modern spectrometers, these exercises

are not needed since the operator simply needs to dial up the nucleus of interest and proceed with the experiment.

With this capability, we sought to develop NMR spectroscopy as a means of characterizing metal sites in zinc- and calcium-dependent proteins. This work was initiated in collaboration with Professor Jerry Odom of USC and Professor David Behnke when he was at USC. The overall objective of this research is to develop NMR methods to a point where they can be used to study the metal sites in diamagnetic metalloproteins. The metals of initial interest have been zinc and calcium. In the past 20 years, we³ and others⁴ have developed and utilized Cd^{2+} via ^{113}Cd NMR spectroscopy as a 'spin spy' to study the Zn^{2+} and Ca^{2+} sites in metalloproteins. The reasoning behind this strategy is the fact that Zn^{2+} and Ca^{2+} have such poor spectroscopic properties. Consequently, a viable alternative is to employ a surrogate probe as a means of studying these metals in this important class of biological systems. In every case studied to date, the surrogate strategy has worked, i.e. it has provided results which are consistent with the known chemistry of the system of interest. This progress has come about as a result of single-crystal measurements³ where a comparison between structure and shielding can be examined. It is the combination of solid- and liquid-state NMR methods which has made ^{113}Cd NMR a valuable structural probe.⁴

Currently, we are taking our qualitative structural correlations obtained from our single-crystal investigations³ of ^{113}Cd shielding tensors and investigating the utility of recent ab initio theories of chemical shielding⁵ in predicting these experimental trends.

Emsley, James W.: Having Fun with Liquid Crystals

James W. Emsley

University of Southampton, Southampton, UK

In the end is my beginning. This is probably true for most scientists in that our ideas have developed continuously from our postgraduate work to what is currently occupying our minds. The closeness of the end to the beginning can suggest an absence of development, but this would be to ignore the richness of the journey. I started research in Leeds in 1956 as a postgraduate student supervised by John Smith, who had recently moved there from Oxford where he had been a student of Rex Richards, doing some of the first applications of NMR in chemistry. My doctoral work involved proton NMR of single crystals of thiourea, urea, and formamide, and the particular interest was to characterize the bond rotational motion in these amides. These studies impressed upon me the usefulness of the dipolar interaction for characterizing molecular motion, particularly if single crystal samples are used. I am still exploiting the dipolar interaction, but now with liquid crystalline samples, and here too the most important contribution that NMR can make is in characterizing the internal modes of motion. Summarized in this way it seems a small step from studying solid crystals to liquid crystals, but the route has been both more challenging and stimulating.

Those early experiments were done on a homebuilt spectrometer, operating at 16 MHz in a field of 0.3 T, and all the analysis of the data was done with planimeters to measure spectral moments and mechanical calculators to fit these to those predicted by models of the motion. Electronic computers became available in Leeds in about 1957 and it then became relatively easy to solve Schrödinger's equation for groups of interacting spins. I can still recall how exciting the future prospects for the application of NMR seemed, which until this advance was limited to analyzing the spectra only of very simple spin systems.

When I left Leeds in 1960 it was at the beginning in Britain of the advent of high-resolution liquid state NMR. Commercial spectrometers were appearing, and I went to Liverpool where Les Sutcliffe had been exploring applications in chemistry with a Varian spectrometer, operating at 40 MHz, which was high field in those days, and about to be upgraded to 60 MHz. It was here that I met Jim Feeney, who had just completed his Ph.D. and who was a newly appointed assistant lecturer, and Neville Boden, who was just starting as a research student. I was to spend almost two years in Liverpool, and the most important outcome was the writing of the book *High Resolution NMR Spectroscopy*. The book originated in an approach to Les Sutcliffe by Pergamon Press, the new publishing house founded by Robert Maxwell. The writing had commenced before I arrived in Liverpool, involving Jim Feeney and Joe Lee, who had preceded me as a postdoc. and who had left to take up a lectureship at UMIST. Joe eventually decided not to continue and I was asked to take his place. It was a daunting task and I was very conscious of my inadequate background for writing a text to cover the whole of this relatively new subject. It was, however, extremely stimulating

and a wonderful way of learning about the capabilities of NMR then apparent. The book was started by the three of us in about 1961 and was finally published in 1965, three years after I had left Liverpool and was in Durham. It had been initiated by Les and he was largely responsible for ensuring that it did appear eventually. Les was also the initiator of our review series, *Progress in NMR Spectroscopy*, suggesting that this would provide a continuing source of authoritative articles on NMR. The first seven volumes appeared at approximately annual intervals and provided another invaluable learning experience, not least in that authors almost always underestimate the time it takes to write a review and completing volumes can be an editor's nightmare. We solved this problem by going to the present system of publishing in parts, in effect, becoming a review journal, although a formal change to a subscription-based periodical came later. The series was in an excellent position to benefit from the expansion in the applications in NMR which started in the 1970s, and now we produce six issues per year, having published 25 volumes and over 150 articles by the end of 1993.

I have been extremely lucky in being a participant in two major scientific developments: NMR and liquid crystals. My interest in liquid crystals started in 1963 when I read the paper by Englert and Saupe describing the first high-resolution proton spectrum from a liquid crystalline sample, that of benzene dissolved in a nematic solvent. This brought together the advantages of solid state NMR, in providing structural information via dipolar interactions, and the narrow linewidths of liquid-state NMR. The possibilities seemed very exciting and I resolved to teach myself how to obtain these spectra. I made virtually no progress until moving to Southampton in 1967, where I acquired a Varian HA-100 spectrometer, a postdoc, Tony Storey, who had been trained as an organic chemist and so could make the liquid crystalline compounds, and a colleague Geoffrey Luckhurst, who had been introduced to liquid crystals whilst an undergraduate at Hull, where George Gray was doing his pioneering work which has had such an influence on electrooptic devices. Our first tasks were to learn how to obtain well-resolved proton spectra from liquid crystalline samples, and how to analyze them by modifying LAOCOON. Tony Storey made several liquid crystals to use as solvents and also showed a quite unexpected flair for writing computer programs, so much so that he has spent the rest of his career in the computer industry.

Our work had a tremendous boost when John Lindon came as a postdoc. He had done a year with Ben Dailey at Columbia and so had experience of recording and analyzing spectra. John stayed for five years which were very productive scientifically, especially as he taught me and my students so much; a part of that continuing learning experience which is such an enjoyable part of the life of a scientist. After we had been working together for a couple of years we decided to write a book, *NMR Using Liquid Crystalline Solvents*, which was published in 1975. John left to go to a post at the Wellcome Foundation Research Laboratories, where he has established a reputation in quite different aspects of NMR. We have, however, started once more to do science together and I will return to this later.

The proton spectra from liquid crystalline samples become very complex as the number of interacting spins increases, and in those early days we could not analyze spectra with more than about eight protons but even then the spectra often defied analysis. It was obvious that the range of application

of proton LCNMR would remain limited to small molecules unless this limitation could be overcome. It seemed to me that the spectra could be simplified by partially deuterating and removing the ^1H – ^2H dipolar interactions by irradiating the deutron resonances. The deutron spectra are dominated by the quadrupolar interaction and are essentially doublets for each group of nonequivalent nuclei, with splittings of typically several kHz. Anderson and Nelson in 1963 had suggested that in such cases decoupling was more efficient if the irradiating signal was modulated so as to produce sidebands at the doublet frequencies. I persuaded a colleague in the Department of Electronics, Trevor Wilmshurst, to design and build a modulator and he suggested that we use phase rather than amplitude modulation. The experiment worked and we sent a note to *Chemical Communications* in July 1971 showing a simple example. In August I attended the 4th ISMAR Meeting in Israel and learned from Saul Meiboom that they had also done a successful deuterium decoupling experiment, but without using modulation. They had simply irradiated at the center of the ^2H spectrum and the good decoupling achieved was attributed to the excitation of double quantum transitions. They had also in fact done a cleverer experiment in another sense. They took 98% deuterated cyclohexane so that decoupling the deuterons gave a proton spectrum consisting of a single line from $\text{C}_6\text{D}_{11}\text{H}$ and doublets from the 18% of the molecule which contain just two protons. This experiment has proved extremely useful. Single frequency decoupling with modern probes is now quite easy, and we regularly obtain well-resolved spectra from eight or even more coupled spins. It is also now much easier to do the modulated decoupling experiment, but using frequency switching rather than phase modulation.

The other major development which has proceeded alongside the experimental improvements has been in our understanding of how dipolar and quadrupolar couplings are related to the structure and orientational order of molecules which have some form of internal motion. In the early days, the view of those using NMR to study dissolved molecules was that the orientational order of a flexible molecule could be described by a single matrix, and that the number of nonzero independent elements reflected an effective symmetry produced by the internal motion, if this was faster than the overall, molecular reorientational motion. Burnell and de Lange convincingly demonstrated inconsistencies in this approach and in its place they proposed a theory which still invoked the kinetics of the molecules. It seemed to Geoffrey Luckhurst and me that this was a complicated way of approaching the problem. We published an alternative theory in 1980 which used equilibrium statistical mechanics to describe the averaging of such interactions as the dipolar and quadrupolar couplings, and this approach seems to have become the accepted way of looking at this problem. The consequence of this theory is that to average dipolar coupling requires a model for predicting how the orientational order is coupled to the internal degrees of freedom in the molecule. Our own approach was developed from the work of Marcelja, who had published a seminal paper in 1974 describing a model for the ordering of alkyl chains in liquid crystals which used a potential of mean torque, U , constructed by adding contributions from the alkyl C–C bonds to that from an aromatic core of the molecule. In fact, the idea of additive contributions to U had also been proposed by Saupe and Nehring as early as 1969 for rigid molecules.

Our early work on flexible molecules was concerned with pure liquid crystals, and at that time the only practical way of studying such complex molecules was to use deuterium NMR. The use of deuterium NMR to study liquid crystals dates from 1965 and a paper by Rowell, Phillips, Melby, and Panar. It was only in the 1970s, with the advent of pulse FT NMR, that ^2H became an easily studied nucleus and then there was a rapid increase in the applications to liquid crystals.

Our own early work used a Varian XL-100, which had a $50\text{ }\mu\text{s}$ 90° pulse for ^2H , a spectral width limited to 25 kHz, and no disk system. In 1979, however, I acquired a Bruker CXP-200 and this made ^2H NMR a much easier nucleus to study. The CXP also had a disk and a programmable temperature controller, making it possible to explore the temperature dependence of orientational order or relaxation rates. The year 1979 also marked the arrival in Southampton of David Turner, and his expertise in FT and 2D techniques enabled us to explore some new applications of NMR to liquid crystalline samples. I was also fortunate in having a graduate student, Tony Avent, who had spent a year working with Ray Freeman. Together we had great fun trying out new experiments. One of the more successful was to use a $90^\circ - \tau - 180^\circ - \tau$ echo sequence with single point acquisition to obtain proton spectra of deuterated samples which were free from proton–deuterium spin coupling: ‘decoupling’ without irradiating at the nonresonant nuclear frequency. Moreover, coupling to all nonresonant nuclei was removed and so spectral simplification could be achieved, for example, in samples containing protons, fluorine, and deuterium. The major disadvantage of this method, however, was the time taken to obtain a spectrum, which was typically several hours.

Our second year with the CXP coincided with Peter Beckmann spending a sabbatical in my lab. Peter had been a graduate student with Myer Bloom and had several years experience of solid state NMR, particularly with measuring and interpreting relaxation rates. We decided to see what new things could be done for liquid crystals. I had been tremendously impressed by the work done by Bob and Gitte Vold and David Grant on measuring spectral densities on small molecules dissolved in liquid crystalline samples, and it seemed to me that it would be fun to try similar experiments on the deuterated liquid crystals which we had used in our studies of orientational order. We were able to demonstrate that Jeener–Broekaert experiments could be applied to obtain $J_1(\omega_0)$ and $J_2(2\omega_0)$ for each site containing deuterium, which was simply repeating what had been done for small molecules, but also that selective inversion–recovery experiments were an alternative way to obtain these data. The interpretation of the large data sets obtained was far more problematic since the relaxation rates depend upon whole molecule reorientational motion, internal motion, and possibly on collective modes of motion, known as director fluctuations. Our first attempt to understand our newly acquired data ignored director fluctuations as a relaxation mechanism and showed that a simple model of superimposed motions, which Peter Beckmann had used in studies of solids, accounted for the main trends in the data. We were always conscious that our neglect of director fluctuations was probably not justified, but we could not see a simple way of accounting for its effects in these complex molecules. The theories available at the time had been developed for rigid, cylindrically-symmetric molecules and extending them to flexible molecules with no

symmetry has still not been attempted. This venture into relaxation has been immensely rewarding for me in that it not only introduced me to some fascinating problems, but I have also come to know such lively people as Bob and Gitte Vold, Pier-Luigi Nordio, Ron Dong, Jack Freed, and Frederick Noack. More recently, it has stimulated me to learn about computer simulation techniques, particularly from Dominic Tildesley, and with him and Bill Palke, who spent a sabbatical in Southampton in 1989–90, to investigate how they can be used to study molecular dynamics and hence to test the analytical theories of relaxation processes.

The 1980s were very productive years for the NMR of liquid crystals. Many labs acquired access to new equipment and the interest in the subject expanded in parallel with an explosion of interest in liquid crystals generally. In Southampton we explored new applications of NMR to these materials, our particular interest being to show how experiments could be used to test molecular theories. Geoffrey Luckhurst, with his wide-ranging interests and knowledge of liquid crystallinity, was a constant source of ideas and together with some excellent students we had an exciting time showing how NMR can give unique insights into the behavior of the molecules in these phases. The availability of high-field spectrometers enabled us to demonstrate how field-induced quadrupolar splittings of deuterium can be used to study pretransitional phenomena in the isotropic phase of nematogens, and we also demonstrated how electric field-induced splittings can be monitored by NMR. We were like children discovering new, untouched playgrounds, with many toys with which to excite our imaginations. We ventured into the use of pressure as a variable, showing the advantages of using deuterium to obtain site-specific data with which to test theories. The pressure probe was built by ‘Tim’ Timimi, a refugee from Saddam’s Iraq, a gifted experimentalist who also played a key role in bringing social cohesion to a diverse research group.

To conclude, I want to relate the story of the Italian connection which has been such a stimulating and successful collaboration. It started when Gian Franco Pedulli came to Southampton from Bologna in about 1968 to work with Geoffrey Luckhurst on ESR. Franco then encouraged a student, Claudio Zannoni, to do a Ph.D. with Geoffrey. Meanwhile, I met a colleague of Franco’s, Ludovico Lunazzi, at the ISMAR Meeting in Israel in 1971, and he suggested that we should collaborate on some NMR studies of solutes with the aim of determining their structures. Ludovico is an organic chemist with considerable expertise in both ESR and NMR, and the collaboration made good sense. We obtained a NATO grant and for the next few years spent a week or two each year in each other’s labs. Through Ludovico I met Carlo Alberto Veracini who works in Pisa, and I added another lab to my Italian connection and became familiar with a second, beautiful Italian city. A former student of Alberto’s, Marcello Longeri, then obtained a fellowship to enable him to spend a year in Southampton and he arrived with his wife Grazia in 1977.

Marcello has an uncanny ability for analyzing impossibly complex NMR spectra. He wrote improved versions of our old spectral analysis programs, combining magnetic equivalence with reflection symmetry so that larger spin systems could be analyzed on the available computers. He works in Calabria, the toe of Italy, and over the last 16 years we have maintained a close collaboration; more recently this has also involved Giorgio Celebre and Pina De Luca. In recent years our work has concentrated on attempts to use NMR to characterize the bond rotational potentials within molecules via the dipolar couplings. This has proved to be particularly interesting, and has involved Claudio Zannoni in Bologna as well as Alberto Veracini’s group in Pisa. John Lindon, my old colleague, is also involved, not only directly in doing experimental work, but also in being the industrial partner in a CASE project which partially supports a graduate student, Lizzy Foord, who is exploring the use of this method to study molecules with therapeutic properties.

In 1984 Alberto Veracini and I organized a NATO ASI at San Miniato on the NMR of liquid crystals at which Claudio Zannoni gave a series of lectures on how to describe the orientational order in rigid and flexible molecules. He mentioned too that it should be possible to obtain a conformational distribution directly from the experimental data, such as dipolar couplings, D_{ij} , by using the maximum entropy principle. He and Alberto, together with Claudia Forte and Lorenzo Di Bari from Pisa, demonstrated this idea on the D_{ij} value obtained for 3-phenylthiophene dissolved in a liquid crystalline solvent. This maximum entropy (ME) method can be thought of as ‘model-free’, compared with the methods developed at Southampton and elsewhere which I describe as additive potential (AP) methods and which are model-dependent. In recent years the groups in Pisa, Calabria, and Southampton have explored the relationship between AP and ME, at first by seeing if the same conformational distribution is obtained by the two methods from the same data, and very recently by showing in a joint publication in the *Journal of Physical Chemistry* how the two methods are related.

This Anglo–Italian collaboration demonstrates how science is about people interacting, testing out ideas on one another, and synthesizing new ideas as a result. It also shows the truly international nature of science.

Engelhardt, Günter: Silicon-29 NMR of Silicates: From Liquids to Solids. An Historical Perspective

Günter Engelhardt

University of Stuttgart, Stuttgart, Germany

The history of the application of silicon-29 NMR to silicates began as early as 1956 when Holzman et al.¹ published the ²⁹Si chemical shifts of an impressive variety of solid and liquid silicon compounds, including quartz, cristobalite, amorphous silica, silicate glasses, and a sodium silicate solution. However, owing to the poor spectral resolution and the low sensitivity of the NMR equipment available at that time, the potential of ²⁹Si NMR in silicate research was not further exploited until, in the early 1970s, the pulse Fourier transform technique was developed and applied in commercial high-resolution NMR spectrometers. In 1973, our group at the Academy of Sciences of the GDR in Berlin-Adlershof was happy to receive a brand-new JEOL FT NMR spectrometer and as soon as the instrument was running we first started ²⁹Si FT NMR experiments on various types of silicon compounds, liquids or solutions, since at that time chemical applications of high-resolution FT NMR were restricted to the liquid phase.

In addition to organosilicon compounds and silicone polymers, we also studied several aqueous sodium silicate solutions and it was quite a surprise to observe numerous sharp and well-resolved resonances in the spectra of some of the solutions. This observation was of particular interest since evidence from other techniques such as Raman spectroscopy, paper chromatography, trimethylsilylation, and reaction with molybdic acid strongly suggested the presence of a distribution of oligomeric silicate anion species in aqueous silicate solutions. However, the structural characterization of individual anion types by these techniques appeared to be difficult. Further systematic studies, carried out in close cooperation with W. Wieker and D. Hoebbel from the Institute of Inorganic Chemistry of the Academy, soon revealed that the various resonances in the ²⁹Si FT NMR spectra of a series of sodium silicate solutions of different composition arise from distinct $Q^n(\equiv(\text{SiO})_n\text{Si}(\text{O})_{4-n})$ groups in a variety of oligomeric silicate anions.

The results of these early studies were published in 1974² and, most notably, two further papers on the same topic but from two other groups appeared in the same year.^{3,4} In subsequent years, numerous detailed ²⁹Si NMR studies of silicate solutions were carried out by various authors which established the identities of a large variety of oligomeric silicate anions of different structures. In particular, Harris and Knight⁵ were able to identify 19 anionic structures in ²⁹Si isotope-enriched potassium silicate solutions, and Knight⁶ confirmed these structural assignments and identified four new silicate species by two-dimensional COSY experiments. Moreover, the dependency of the anion distribution on the chemical composition of the silicate solutions, the specific structure-directing effects of various cations, the dynamic

exchange processes of SiO₄ tetrahedra between distinct silicate anions, the condensation reactions of silicic acids, the formation of dissolved aluminosilicate anions, and other interesting features of the solution chemistry of silicates were investigated in detail. Altogether, an exciting wealth of new information on the structure, reactivity, and dynamics of silicate anions not amenable by other techniques could be derived from the ²⁹Si FT NMR studies of silicate solutions⁷ which even nowadays attracts considerable interest.

Since most of the silicates occurring in Nature and used in a wide range of technical applications are solids, it was obvious from the very beginning of the above mentioned liquid state ²⁹Si NMR studies that the high potential of ²⁹Si NMR in providing detailed information on silicate structure should be extremely useful if it could also be applied to solid silicates and aluminosilicates. However, although the principles of magic angle spinning and cross-polarization techniques were already known to be effective means for line narrowing and sensitivity enhancement in solid state NMR spectra, high-resolution NMR of solids in general, and that of ²⁹Si in particular, was not yet well developed in the early 1970s. At that time we had already had for several years a very fruitful cooperation with the group of Endel Lippmaa at the Estonian Academy of Sciences in Tallinn on the application of multinuclear liquid-state FT NMR to various organic, elementorganic, and inorganic compounds, including ²⁹Si NMR of organosiloxanes and silicates. Encouraged by the first successful experiments of the Tallinn group with the combination of MAS and CP techniques in measurements of high-resolution solid state ¹³C NMR spectra of powder samples,⁸ we decided in 1977 to carry out systematic studies on the general applicability of these methods to organic and elementorganic solids and, in particular, to solid silicates.

For the initial experiments, a 0.94-T large-gap electromagnet and a homebuilt air-driven MAS turbine with 10-mm o.d. glass rotors, rotated at speeds up to 4 kHz in a double-tuned crossed-coil probe with adjustable angle of the spinning axis, was used in Tallinn. The rf pulse sequences were generated by a modified NIC-293 input-output device, connected to a NIC-1085 computer which was also used for signal accumulation and the fast Fourier transform. While this equipment worked well for ¹³C CP MAS NMR of organic solids, first attempts to measure ²⁹Si CP MAS NMR spectra were not successful. However, after several months of cumbersome work improving the performance of the spectrometer and the mechanics of the MAS probe, we succeeded in the summer of 1977 in measuring the first highly resolved ²⁹Si CP MAS NMR spectra of solid silicates and organosilicon compounds.⁹ This success was mainly due to the skilful activities of the late Mädis Alla, of Tiit Tuherm and of other members of the Tallinn group in the development of the MAS equipment and the high-power spectrometer electronics.

A considerable step ahead was the installation in Lippmaa's laboratory of a Bruker CXP-200 solid state high-resolution spectrometer equipped with a superconducting 4.7-T wide-bore magnet and a MAS probe for conical Andrew-type rotors manufactured from Delrin. Using this instrument the ²⁹Si MAS NMR and CP MAS NMR spectra of an extended series of solid silicates and aluminosilicates of natural and synthetic origin were measured in 1979,¹⁰ followed by a detailed investigation of a number of aluminosilicate zeolites in 1980/81.¹¹ These studies clearly demonstrated that the main

characteristics of the ^{29}Si NMR spectra of silicate solutions can also be applied to the interpretation of the spectra of solid silicates, and that additional information can be derived on specific structural features of the solids such as the distribution of silicon and aluminum in aluminosilicates, and the presence of crystallographically inequivalent Si sites. Starting from this pioneering work in the years 1980–81, high-resolution solid state ^{29}Si NMR has emerged rapidly as an extremely useful and widely applied tool for the structural characterization of a wide range of crystalline and amorphous silicates and related materials.⁷ This progress is demonstrated in more detail by the following related articles in this Encyclopedia, see **Silicon-29 NMR of Solid Silicates, Amorphous Silicon Alloys, Silica Surfaces: Characterization and Geological Applications**.

Ernst, Richard R.: The Success Story of Fourier Transformation in NMR

Richard R. Ernst

Eidgenössische Technische Hochschule, Zürich, Switzerland

This chapter could also be entitled: How to be successful by borrowing clever ideas. During my undergraduate studies at the Swiss Federal Institute of Technology in Zürich (ETH Zürich) from 1952–56, the term nuclear magnetic resonance was never even mentioned, and when I started my thesis with Professor Hans H. Günthard in 1958 after some healthy military training I knew nothing about my beloved future companion NMR. It was, so to say, a marriage arranged by my thesis advisor. Fortunately, an extraordinarily gifted, truly ingenious scientist, Hans Primas, was just in the course of finishing the construction of the first Swiss high-resolution NMR spectrometer. I had the enormous luck to work under his guidance on my Ph.D. thesis for the following 4 years.

HANS PRIMAS AND HIS NMR SPECTROMETERS

Professor Hans H. Günthard, at that time Associate Professor in the Laboratorium für Organische Chemie, later Head of the Laboratorium für Physikalische Chemie, was an enormously enterprising and stimulating leader (Figure 1). He set out to introduce all powerful modern spectroscopic tools into the Swiss university chemistry. It should also be mentioned here that he was strongly encouraged by Professor Leopold Ruzicka who was heading the Laboratorium für Organische Chemie with much foresight. At the early date of 1953, Professor Günthard asked Hans Primas to pioneer the construction of a high-resolution NMR spectrometer useful for chemical applications (Figure 2). During a brief stay at the University of Zürich in 1953 with Professor Hans Staub, who was a former co-worker of Felix Bloch at Stanford, and with his associate Ernst Brun, Hans Primas was exposed for the first time to the practical aspects of NMR, here in the hands of enterprising solid state physicists.

The 25 MHz proton resonance spectrometer that Primas and Günthard constructed used a 0.6 T permanent magnet (Figure 3), spherical sample containers to improve the magnetic field homogeneity,^{1–4} and a field flux stabilizer.⁵ It was an important event when in 1956, Günthard and Primas convinced the Swiss company Trüb-Täuber, with its scientific director Dr. L. Wegmann, to manufacture and commercialize this spectrometer under the name KIS I.⁶ Several instruments of this type were sold in Europe during the following years.

Hans Primas decided to continue his engineering ventures by designing a high-field instrument working at 75 MHz proton

Figure 1 Professor Hs.H. Günthard, the spinning nucleus of the research group in 1958

Figure 2 Professor Hans Primas working on his electronic design for the 25 MHz NMR spectrometer in 1958

resonance, and he developed a new concept of shaped pole caps for electromagnets to achieve high-field homogeneity by avoiding local saturation.⁷ This spectrometer was also commercialized as KIS II, operating at a proton resonance frequency of 90 MHz.

The company Trüb-Täuber was dissolved in 1965, and its NMR spectroscopy division became the germ for the well-known Swiss company Spectrospin AG in Fällanden, which is a member of the Bruker group. In some sense, the instruments built by Hans Primas are the ancestors of the modern high-resolution Bruker-Spectrospin spectrometers. Besides numerous instrumental innovations, Hans Primas also contributed during this time to new theoretical concepts such

Figure 3 The 6 kG permanent magnet for the 25 MHz proton magnetic resonance spectrometer in 1958. The coils for the magnetic flux stabilizer are visible on the pole pieces. The probe assembly is directly attached to the preamplifier. The radiofrequency transmitter stands on top of the magnet

as a generalized perturbation theory in operator form⁸ and superoperator concepts for calculating NMR spectra.^{9,10}

FIRST VENTURE IN STOCHASTIC RESONANCE

I never even started my first thesis subject posed by Professor Günthard in 1958, i.e. a group theoretical analysis of NMR spectra. After extensive ventures into electronics and the construction of NMR probe assemblies, frequently burning my fingers with solder and high voltages, I finished my graduate studies in 1962 with a purely theoretical investigation of stochastic magnetic resonance. The pertinent ideas for this study came from Hans Primas, who at that time was working on the theory of quantum mechanical systems with a stochastic Hamiltonian,¹¹ inspired by the work of Norbert Wiener¹² and others.

The application of stochastic excitation for obtaining spectral information with an inherent multiplex advantage was not considered at that time. Rather, stochastic excitation was intended for decoupling purposes. By a broadband excitation of all spins except for one within a homonuclear spin system, broadband spin decoupling of this selected spin was

attempted. Sweeping a broadband frequency source with a narrowband hole in its spectrum through the entire spectral range should lead to a completely decoupled homonuclear spectrum, which could be observed with a weak coherent irradiation in the center of the hole. It was disappointing for us to recognize that the principle only functions for weakly coupled spin systems, a situation that needed, in our view, anyway no further simplification. Weak coupling was too simple to appeal to us, and we missed the possibility of inventing stochastic heteronuclear decoupling. No wonder that we never did a stochastic resonance experiment. Our aim was more a theoretical excursion to explore the nonlinear stochastic response of a quantum mechanical system by means of an example.¹³

THE SENSITIVITY DEFECT OF NMR

Anyone who performed NMR experiments in the 1950s will remember the exceedingly low sensitivity of NMR at that time. A signal-to-noise ratio of 5:1 for the spectrum of a 1% ethylbenzene solution was considered to be excellent. Indeed, nobody could envision the 1000-fold increase that would happen in the next 30 years. We thought a lot at that time about sensitivity enhancement techniques. Special \hbox{low-noise} preamplifiers using ceramic tubes of the type 7077-G-E-60-17, optimized probe assemblies, and electronic filtering techniques were considered.¹⁴ Noise calculations of probes and of complete spectroscopic experiments were a daily routine in the laboratory of Professor Günthard. This was normally the last resort for completing a Ph.D. thesis if the constructed spectrometer did not perform properly. However, this taught us more about response theory, Fourier transforms, and noise figures than any working spectrometer would have done.

This was the time of the computer of averaged transients, CAT, which helped to improve sensitivity by the coaddition of slow passage spectra.¹⁵ At that time we advanced the idea of using one ultraslow passage instead of repeated scanning through the same spectrum. In this way we missed some important facts that became clear to me only after my arrival in the fall of 1963 at Varian Associates in Palo Alto for my postdoctoral years.

Under the guidance of Dr. Weston A. Anderson, I started extensive investigations of rapid scan performance conditions based on numerical solutions of the Bloch equations. They revealed the possibility of significantly enhancing the sensitivity per unit time by rapid and repetitive scanning through the spectrum,^{16–18} facts that were already well known to scientists such as Bitter¹⁹ and Jacobsohn and Wangsness.²⁰ However, at that time nobody recognized the possibility of using computers to remove the distortions which the rapid scan introduced into the spectrum.

FOURIER TRANSFORM NMR SPECTROSCOPY

I remember in the spring of 1964, when the calculations of performance conditions were in full progress, Wes Anderson

Figure 4 Dr. Weston A. Anderson and his Little Devil Prayer Wheel which he constructed for multiple channel NMR spectroscopy in 1963

came to me and mentioned the possibility of applying repetitive pulses for the simultaneous excitation of all nuclear resonances and using a computer to analyze the response. I was asked to sign, as a witness, the important notebook pages by Wes Anderson that contained the principles of pulse Fourier spectroscopy. I was not very aware at that time of Wes's previous work on the Wheel of Fortune (Figure 4); in fact, I never saw it. I do not remember whether Wes showed me at the same time or slightly later the highly important patent application by Russell Varian²¹ which already contained the basic idea.

There was no rf pulse equipment available at Varian at that time as everybody was fully devoted to continuous wave spectroscopy. However, as a result of masterly support by the electronic engineer William Siebert, within two months a proton-pulse spectrometer with 300 W pulse power using a fluorine field/frequency lock without any magnetic field modulation was assembled.

The crucial first experiments were performed during the summer months of 1964 while Wes Anderson was on an extensive journey abroad (Figure 5). When he came home, I was able to hand him the first successful results that surprised me as much as him. However, there was no reason to be overenthusiastic and we certainly did not think in terms of a champagne party. When one considers the cumbersome treatment of the data acquired in a time averaging CAT 400 computer, into paper tape, being converted into punched cards at IBM San Jose, then converted to magnetic tape at the Service Bureau Corporation, Palo Alto, Fourier-transformed

Figure 5 Early experiments performed on 16 September 1964. After a few experiments on benzene, a complicated spin system, 1-bromo-4-fluorobenzene, was also treated on the first day. The figure shows the FID and a CW spectrum. The Fourier transform of the FID has been lost

Figure 6 The author in front of the modified DP-60 NMR spectrometer on which the first Fourier transform NMR experiments were performed at Varian Associates, Palo Alto, CA, in 1965. The author is acting as a human interface between the time averaging computer C1024 and an IBM card punch

on an IBM 7090, and plotted on a Calcom plotter, nobody could have been convinced by us of a time-saving advantage! Later, we had our own card punch to shorten the data pathway (Figure 6).

Nevertheless, we decided to publish the work in the *Journal of Chemical Physics*. However, we had no success; the paper was rejected twice, being considered too technical and not of sufficient originality. We then submitted the paper to *Review of Scientific Instruments* on 9 July 1965 where, after further revision, it was finally accepted on 16 September 1965.²²

I also discussed the subject at the 6th Experimental NMR Conference in Pittsburgh, 25–27 February 1965. In general the response was not overwhelming, except from a few people with foresight like Oleg Jardetzky. The Varian management was also not too excited. With little enthusiasm, an accessory was developed for the HR-100 spectrometer; however, that never performed properly. Even the newly developed XL-100 concept, which was worked out in the following years, was designed with a field-modulation system that prohibited the implementation of pulse Fourier transform spectroscopy. Ultimately, it was the competitive German company Bruker Analytische Messtechnik with Toni Keller and Professor Günther Laukien which demonstrated and sold the first properly designed Fourier transform equipment in 1969. With much foresight, they brought the first Fourier-transform-only spectrometer HX 90 onto the market in 1971.

HETERONUCLEAR NOISE DECOUPLING

Being out of better ideas for the time being, it was tempting in May 1965 to try some of the ideas left over from my thesis,¹⁴ thus justifying post mortem my otherwise spoiled best years. Broadband spin decoupling indeed appeared to be a worthwhile goal to me, especially for heteronuclear spin systems. The first experiments concentrated on a fluorine–proton system. The necessary binary random noise was taken initially from the even/odd character of the last digits in the Palo Alto telephone directory, modulated onto the radiofrequency carrier, and applied to the protons, observing the fluorine resonance at the same time.²³ This led to the initial pseudonym phone-book resonance. Only later was I informed by R. Whitehorn (Varian Associates) that binary noise could be generated in a more convenient and predictable manner by shift register generators²⁴ that were used from September 1965 onwards.

Numerous further modulation schemes such as repetitive 180° and other pulses were used and it was found that primarily the spectral properties had a significant effect, but otherwise the type of sequence was immaterial. There was no indication whatsoever in my experiments for the dramatic improvement that was discovered much later by Malcolm Levitt and Ray Freeman²⁵ using composite pulse sequences.

COMPUTERIZED SPECTROSCOPY

Until 1966, Varian Associates did not possess even a single computer, and all the Fourier NMR experiments I undertook at Varian used off-company data processing. Finally, in October 1966, the first PDP8 computer with 4096 words of 12-bit memory arrived, and I interfaced it with the help of William Siebert to the most widely used routine NMR spectrometer, the A-60. This prohibited the use of pulse Fourier transform experiments for which the A-60 is unsuited by design. Numerous other applications were programmed and tried in a rapid sequence in view of a presentation at the 8th ENC, 2–4 March 1967, in Pittsburgh.

The experiments included signal averaging with automatic drift compensation by searching for the TMS line, resolution

enhancement by convolution, spectra analysis by multiplet identification, coding of spectra for a subsequent automatic library search, automatic 2D shim mapping, and automatic shimming by use of the simplex search algorithm. Except for the automatic shimming procedure,²⁶ this work was not published at that time as it was felt to be of little originality. A later account can be found in Ref. 27.

RETURN TO THE HOMELAND

My return to Switzerland in the spring of 1968 proved to be a scientific disadvantage. Unsuitable equipment and the lack of support at the Laboratorium für Physikalische Chemie, ETH Zürich, made progress difficult. I had to supervise an ill-suited Varian 220 MHz spectrometer that was strictly limited to continuous wave operation without a field/frequency lock system. With a streetcar line in the neighborhood, this turned out to be a disaster. Despite a homemade lock system, the spectrometer never performed satisfactorily. Scientific output was low, and after two years of struggling I was affected by a nervous breakdown in 1970.

Looking back, I am tempted to rate my years from 1968 to 1974 as the dark Middle Ages after the productive and inspiring classical years in Palo Alto. We tried numerous new approaches, but none with an epoch-making breakthrough. (Personally, I became interested in the mysterious and fascinating Tibetan art during this time period.)

With my first graduate student, Thomas W. Baumann (thesis 1969–74), we ventured on our first exploratory excursion into solid state NMR, constructing a 1.5-T solid state spectrometer. We devoted much time on cross polarization in the laboratory frame ($^{35}\text{Cl} \rightarrow ^1\text{H}$) and in the rotating frame ($^1\text{H} \rightarrow ^{13}\text{C}$). Our time-consuming solid state activities became more exciting in 1973 with the work of Luciano Müller which will be described later.

My second graduate student, Dieter Welti (1970–76), together with Max Linder, explored the use of paramagnetic shift and relaxation reagents in NMR, using borneol and 1-propanol as model compounds. The question of accurate structure determinations using the multifaceted shift and relaxation effects was our primary interest.²⁸

Just to keep our obstinate HR-220 Varian spectrometer busy, we started a series of investigations on simple molecules dissolved in a nematic phase. After the study of a few four-ring compounds by Christian Oertli, we explored, together with Alexander Frey, the distortion of cubic molecules by liquid crystalline solvents.²⁹ Again the determination of molecular structures was our main interest.

I was still interested in the slowly emerging Fourier transform spectroscopy, and I studied some subtle effects of pulse excitation such as the equivalence of slow passage and pulse spectroscopy,³⁰ saturation effects in Fourier spectroscopy, together with my first postdoc Robert E. Morgan,³¹ and the causality principle in Fourier spectroscopy, together with my third graduate student Enrico Bartholdi.³² Motivated by the notorious field instability in Zürich, we also proposed at that time the usage of difference-frequency measurements to avoid the need for a field/frequency lock system.^{33,34}

Another series of studies was devoted to the application of pulse spectroscopy to chemically induced dynamic nuclear

polarization (CIDNP). It appeared to us very natural to investigate time-dependent phenomena with time-resolved measurement techniques. This was the subject of the thesis of Stefan Schaublin (1971–76). For a short period he was supported by Alexander Wokaun.^{35,36} This work also led to the recognition of the important intensity problems when investigating nonequilibrium populations by pulse experiments.³⁷ Later, these studies were extended to stopped flow experiments by René O. Kühne and Thierry Schaffhauser.³⁸

STOCHASTIC RESONANCE

Pursuing my old love and motivated by a correspondence with Wes Anderson, in June 1968 I started the first attempts to compute and measure NMR spectra via stochastic noise excitation of the sample and by Fourier transforming the cross-correlation function that relates input and output noise.³⁹ The first experiments already used shift register sequences as sources of binary pseudorandom noise.²⁴ At virtually the same time, Reinhold Kaiser also proposed stochastic resonance for recording spectra, but using Gaussian noise to excite the spin system.⁴⁰

Subsequently, the theory of stochastic resonance was worked out in great detail in the thesis of Enrico Bartholdi (1971–75) and by Alexander Wokaun.⁴¹ Experiments have been performed by Kurt A. Meier and Marco Genoni.

Although the properties of higher correlation functions were well known to us at that time, we did not recognize that they contain multidimensional information that could be used and displayed in the form of 2D spectra. This became obvious to us however, in the course of the early calculations of Enrico Bartholdi in 1972 in the context of two-pulse 2D Fourier spectroscopy.⁴²

THE DAWN OF TWO-DIMENSIONAL SPECTROSCOPY

The participation of Thomas W. Bauman at the AMPERE Summer School in Basko Polje, Yugoslavia, in September 1971 was an extremely fortunate event. Being a meticulous scientist, he brought home a careful script of the lectures, among them one by Jean Jeener that attracted my attention immediately: a simple two-pulse experiment that produced revealing 2D spectra by 2D Fourier transformation of a 2D set of response signals (Figure 7 and 8).

This was exactly the technique I had been waiting for. I had been thinking for some time about systematic computer-controlled double resonance experiments, but appreciated the complexity of the resulting 2D spectra should they follow the shape of the famous Anderson–Freeman plots.⁴³ The Jeener two-pulse experiment appeared not to have this disadvantage.

Enrico Bartholdi, who had just started his graduate studies, was willing to perform some analytical calculations on two-pulse experiments, taking relaxation into account. He confirmed the principal usefulness of the experiment and studied its features in detail. We did not plan to perform

Figure 7 Professor Jean Jeener, the inventor of two-dimensional Fourier transform NMR

Figure 8 Thomas Baumann (right) and the author trying to understand the notes of the AMPERE Summer School on the two-pulse experiment proposed by Jean Jeener in 1971. In the background is the modified DP-60 Varian NMR spectrometer on which the first two-dimensional NMR experiments were performed

experiments for two reasons. First we considered 2D spectroscopy as Jeener's property and waited for his results to be published. Second, we thought that our computing equipment, with 16 000 words of memory, was inadequate for two-dimensional data storage and processing. We had some correspondence with Jean Jeener on the experiment in 1973, and he showed us a rough draft of an unfinished paper on this subject which, unfortunately, was never published.

In 1974, I attended the 15th Experimental NMR Conference (ENC) and heard on 30 April 1974 an exciting lecture by Paul Lauterbur entitled Zeugmatography–Spatial Resolution of NMR Signals. He discussed the attainment of images by the projection–reconstruction method using continuous wave experiments. I immediately recognized that time domain experiments with switched magnetic field gradients in complete analogy to 2D spectroscopy would be the method of choice. This led to the concept of Fourier zeugmatography or Fourier imaging with a patent filed originally on March 18, 1975, and issued on January 24, 1978. As I was acting

Figure 9 Early 2D spectrum of 1,1,2-trichloroethane recorded on 10 September 1974 with the Jeener two-pulse sequence on the spectrometer illustrated in 8. The absolute value spectrum using letter-coded intensities in a contour representation shows two strong diagonal peaks, two cross peaks, and two axial peaks

at that time as a consultant, I assigned it to Varian Associates.

I was now sufficiently motivated to perform 2D spectroscopic and imaging experiments. At the same time, I was also asked by Kurt Wüthrich to present some introductory remarks, possibly on our own work, at the VIth International Conference on Magnetic Resonance in Biological Systems, Kandersteg, 16–21 September 1974, which we organized together with Joachim Seelig. As I did not have anything biological to talk about, I decided to perform rapidly the first 2D and Fourier imaging experiments, both with biological applications in view. I undertook the initial 2D experiments myself on a modified Varian DA-60 spectrometer equipped with a Varian 620i computer with 16 000 memory words (16 bits) using my own software (Figure 9). Using a teletype for letter-coded contour maps, I obtained the first halfway decent spectra on 1 July, 1974. The Fourier imaging experiments were performed together with Anil Kumar on a Bruker SPX4-100 spectrometer equipped with a Varian 620/L-100 computer with 12 000 memory words, using the *x*- and *y*-shim coils of the Varian 15 in. magnet for the switched field gradients^{44,45} (Figure 10). It was little wonder that my rapidly concocted contribution was rated as premature at the Kandersteg conference! Sometimes, however, even prematurely born children survive and excel.

This was indeed the end of my dark middle ages. We had been freed from our one-dimensional narrow-mindedness and had again room to move in new dimensions. Modern times had started without being noticed at that instant. We had some difficulty in appreciating the future as far as these new horizons were concerned, but we very much enjoyed playing with a novel toy that produced fascinating 2D plots and images. We felt at this moment more like graphic artists and playboys than scientists.

PLAYING WITH A NEW TOY

We were indeed fascinated by the wealth of new possibilities offered by the 2D spectroscopy concept. Numerous

Figure 10 One of the very first 2D Fourier images of two coaxial water-filled sample tubes, recorded by Anil Kumar on 10 July 1974 on a modified Bruker SPX4-100 spectrometer. The plot uses letter-coded intensities

homonuclear schemes were explored in the thesis work of Walter P. Aue (1974–79): the detection of multiple quantum transitions,⁴² homonuclear broadband decoupling and *J*-resolved NMR spectroscopy together with Jiri Karhan,⁴⁶ and phase separation techniques together with Peter Bachmann and Luciano Müller.⁴⁷ Heteronuclear experiments were performed by Luciano Müller in his thesis work (1973–77), partially together with Anil Kumar.^{48–51} Andrew Maudsley showed for the first time the possibility of indirect detection of low- γ nuclei,^{52,53} and Alexander Wokaun expanded the techniques and applications of multiple quantum spectroscopy^{54–57} in his thesis (1974–78). He showed for the first time the possibility of phase cycling for the selection of individual orders of multiple quantum coherences,⁵⁵ and demonstrated the usefulness of multiple quantum relaxation.⁵⁶

Competition was not yet a real problem during these early years. Few scientists believed in the future of 2D spectroscopy—with one exception: Ray Freeman and his extremely talented graduate student Geoffrey Bodenhausen (who did his earlier studies in our research group in Zürich). In the design of powerful heteronuclear 2D experiments, in particular, they were very strong,^{58–60} and merit much of the credit for the initial phase in the development of 2D NMR spectroscopy.

The second major 2D spectroscopy technique, 2D exchange spectroscopy, originated from a discussion with Jean Jeener at the Gordon Conference on Magnetic Resonance in 1978. He confessed on this occasion that the three-pulse scheme of 2D exchange spectroscopy was in fact the first that came to his mind before proposing the two-pulse experiment at the AMPERE Summer School in Basko Polje in 1971. With the small molecules to which we were limited in our laboratory, it proved difficult to detect cross-relaxation cross peaks, but Beat H. Meier found it quite easy to observe chemical exchange cross peaks.^{61,62} The special features of this important experiment were worked out subsequently in great detail by Slobodan Macura, Yong-Ren Huang, and Dieter Suter.^{63–68}

Also, at the same time several solid state 2D experiments were investigated, but this work will be summarized later.

EXPLORING THE WEALTH OF MODIFIED 2D TECHNIQUES

While the previous development of 2D spectroscopy had been more or less sequential, the following period rather resembled little Max in Paradise who does not know which fruit to pick and eat first. Development during this time had, in essence, two goals: (i) to increase the information content of 2D spectra; and (ii) to decrease their complexity. I had little personal impact on these developments. A group of extraordinarily creative co-workers determined the direction of our future research efforts. I became more an organizer and trouble shooter.

The first step in increasing the information content was the introduction of a relayed homonuclear coherence transfer step by Geoffrey Bodenhausen together with Günther Eich^{69,70} where a two (or more) pulse sequence leads to a multistep coherence transfer, important for the elucidation of crowded NMR spectra. Similar heteronuclear procedures were proposed by Philip H. Bolton almost simultaneously.⁷¹

The next development was total correlation spectroscopy (TOCSY) in the rotating frame tested for the first time by Lukas Braunschweiler.⁷² Here all the resonances of a coupled spin system are connected by cross peaks. This allows the easy recognition of complete families of coupled spins. Subsequently, considerable work in our group has been devoted to rotating frame experiments, as well as extending the important work of Axel Bothner-By on ROESY.⁷³ Christian Griesinger has introduced procedures for the elimination of frequency-offset effects⁷⁴ and of cross-relaxation effects by Clean TOCSY.⁷⁵ He introduced the invariant trajectory approach for the description of radiofrequency-perturbed experiments.⁷⁶ Jacques Briand further improved Clean experiments by the introduction of Clean CITY,⁷⁷ and Rafael Brüschweiler suggested a novel cross-relaxation measurement technique called T-ROESY.⁷⁸

Another neat experiment, called Accordion spectroscopy and worked out by Geoffrey Bodenhausen,⁷⁹ increases the information content of 2D spectra by incorporating exchange-type information into the 2D peak shape. The resulting spectra effectively represent projected 3D spectra.

An even larger class of experiments allows the simplification of overcrowded 2D spectra for facilitating their analysis. The most successful and general type of simplification scheme is multiple quantum filtering, introduced by Ole W. Sørensen^{80,81} with contributions from Malcolm H. Levitt.^{82,83} The techniques of multiple quantum spectroscopy⁸⁴ and coherence-transfer-pathway selection⁸⁵ are related. In this context Geoffrey Bodenhausen, together with Lukas Braunschweiler and Herbert Kogler, have made a very significant contribution. Further filtering procedures, mainly due to Ole W. Sørensen, are *J*-filters⁸⁶ and *Z*-filters.⁸⁷

The names of Christian Griesinger and Ole W. Sørensen are nowadays closely connected with exclusive correlation spectroscopy or ECoSY,^{88–90} a technique that leads to simplified multiplet patterns in 2D spectra and allows ready

determination of *J* coupling constants. The ultimate forms of ECoSY are bilinear and planar COSY experiments, introduced by Thomas Schulte-Herbrüggen, Zoltan L. Mádi, and Ole W. Sørensen.⁹¹ In this context, the symmetry features of 2D spectra, worked out again in contributions by Ole W. Sørensen and Christian Griesinger together with Claudius Gemperle, Serge Boentges, and Beat U. Meier,^{92–94} are important.

A very drastic simplification of 2D (or 1D) is achieved by spin topology filtration, investigated by Malcolm H. Levitt and Christian Radloff.^{95–99} Here, the coupling network topology is used as a criterion for peak rejection.

In parallel to these predominantly homonuclear experiments, heteronuclear experiments have also been worked out by Ole W. Sørensen.^{81,100–102} His work in this area is summarized in Refs. 103 and 104.

It is not surprising that Malcolm H. Levitt also left in Zürich some composite pulse traces.^{105–108}

Instead of simplifying 2D spectra to allow their manual analysis, it is often possible to devise computer routines for their automatic analysis. Major contributions in this field have been made by Geoffrey Bodenhausen, Beat U. Meier, Zoltan L. Mádi, and Serge Boentges.^{109–113}

It is not possible to mention all the contributions of an astonishingly creative group of enthusiastic co-workers here nor is it possible to make well-deserved cross references to other highly productive research groups.

COLLABORATION WITH KURT WÜTHRICH AND THE APPLICATIONS OF 2D SPECTROSCOPY TO MOLECULAR BIOLOGY

At the end of 1975, the high-field NMR center with the Varian HR-220 spectrometer under our supervision was replaced by a new high-field NMR center with a Bruker HMS-360 spectrometer under the supervision of Kurt Wüthrich. It was desirable at this point for both sides to continue and intensify the collaboration that had existed in a loose form since the inauguration of the high-field NMR center in 1969. It was easy to select 2D spectroscopy as the subject of mutual interest, as it became clear that its application to molecular biology could be fruitful if only the enormous technical difficulties could be solved.

In December 1976, a joint project was started with Peter Bachmann, a very experienced spectroscopist and computer programmer, and Kuniaki Nagayama, a brilliant young Japanese scientist. This was the beginning of an extremely fruitful series of joint projects lasting for 101/2 years. Initially, the projects were supported by ETH Zürich. However, due to a financial bottleneck in the school, the later phases were financed by Spectrospin AG and the Kommission zur Förderung der wissenschaftlichen Forschung.

The initial studies concentrated on the simplification of biomolecular NMR spectra by 2D *J*-resolved NMR,^{114–117} and by the use of selective spin decoupling.^{118,119} The first correlation spectra were recorded in the spin-echo-correlated (SECSY) mode to save performance time and computer memory by restricting the ω_1 domain.¹²⁰

A major breakthrough in 1980 was achieved by Anil Kumar, who had joined the project during his second stay in Zürich. He demonstrated that cross relaxation in macromolecules can be detected surprisingly well with the experiment presently known under the acronym NOESY.¹²¹ This is the 2D version of the 1D transient NOE experiment that Gordon and Wüthrich had previously introduced for studies of proteins.¹²² It is the same experiment that had earlier been used by Jean Jeener, Beat H. Meier, and Peter Bachmann for the exploration of chemical exchange networks.^{61,62} Together with the correlation experiment in the original form proposed by Jeener and known as COSY, Kurt Wüthrich, Gerhard Wagner, and co-workers had all the required tools in their hands in 1980 to develop their ingenious highly successful sequential assignment procedure for biopolymers,¹²³ a task they had already pursued previously using more cumbersome one-dimensional NMR techniques.¹²⁴

Further work undertaken in this series of joint projects concerned quantitative comparisons of 1D and 2D NOE measurements,¹²⁵ strong coupling effects,¹²⁶ an extension of previous 1D NOE build-up rate studies^{122,127} to 2D NMR,¹²⁸ triangular multiplication,¹²⁹ and symmetrization.¹³⁰ The successor to Anil Kumar, Slobodan Macura, was an expert on 2D exchange studies and contributed significantly to the suppression and separation of *J* cross peaks in NOESY spectra.^{131,132} Further important improvements by multiple quantum filtering and multiple quantum spectroscopy were achieved by Mark Rance.^{87, 133–136} Norbert Müller worked out the rules for the appearance of forbidden relaxation-induced cross peaks in 2D spectra,^{137,138} and of cross peaks in multiple quantum filtered spectra.¹³⁹ Finally, Michael H. Frey contributed to more applied projects.^{140,141}

EXTENSION TO THREE DIMENSIONS

For a long time, 3D spectroscopy appeared to be out of reach because of performance–time and storage–space limitations. The first attempts by Christian Griesinger and Ole W. Sørensen in this direction, partially in collaboration with the research group of G. Marius Clore and Angela M. Gronenborn, therefore used selective excitation techniques.^{142–144} Later, however, it was found that nonselective 3D experiments are also quite feasible.¹⁴⁵ This parallels the work by other research groups, in particular by R. Kaptein and A. Bax.

CONFORMATIONAL DYNAMICS OF BIOMOLECULES

During the course of the past five years, our interest has shifted away from the design of pulse sequences for the manipulation of multidimensional spectra. We have become more interested in the study of the intramolecular dynamics of biomolecules. This is a field where much progress is still needed before the motional modes relevant for biological activity can be sufficiently well characterized. To date, much of our work has concentrated on the cyclic decapeptide antamanide, and relevant contributions have

been made by Christian Griesinger, Zoltan L. Mádi, Rafael Brüschweiler, Martin Blackledge, Jürgen Schmidt, Matthias Ernst, Ping Xu, and Tobias Bremi in collaboration with the research groups of Martin Karplus and Wilfred van Gunsteren.^{146–152}

ACTIVITIES IN SOLID STATE NMR

Since my return from California in 1968, our involvement in solid state NMR has been considerable. I often mentioned that although about 70% of our efforts went into solids about 70% of our results came from liquid-state NMR. Solids have proved to be harder and more brittle in our hands than liquids!

After some initial exploratory studies by Thomas Baumann from 1969 to 1974 which have been mentioned earlier, Luciano Müller together with Anil Kumar and Thomas Baumann produced results in 1974 for our very first *Physical Review Letter*,¹⁵³ describing a particularly neat example of transient oscillations in cross-polarization experiments together with a simple explanation.¹⁵⁴ We have not always been so lucky. A somewhat related, but not uninteresting paper on cross polarization with a pulsed radiofrequency field, received a devastating comment from a referee and was never published.

After the success of 2D spectroscopy in liquids, and following some very early work by the research group of John S. Waugh,^{155,156} we also tried to explore possibilities in liquid crystals¹⁵⁷ and in solids.¹⁵⁸ Perhaps the most relevant contribution in this context was the orientation of tensorial interactions based on ridge patterns in 2D powder spectra obtained by Max Linder (thesis 1979–82) and Alfred Höhener.¹⁵⁸ Taking advantage of the newly developed windowless dipolar decoupling multiple pulse sequences by Doug Burum and Max Linder,¹⁵⁹ heteronuclear high-resolution correlation experiments in solids were also explored by Pablo Caravatti, Geoffrey Bodenhausen, and Lukas Braunschweiler.^{160,161}

After the closure of the high-field NMR center in 1975, we converted the HR-220 spectrometer into a solid state ¹⁴N apparatus to observe resolved ¹⁴N double quantum spectra in the hope of developing applications to biomolecules. This turned out to be more difficult than expected. However, these experiments did allow Peter Brunner and Michael Reinhold to explore the mechanism of cross polarization of double quantum transitions.^{162,163}

The attempts of Thierry Schaffhauser to study the one-dimensional organic conductor bis(tetrathiotetracene) triiodide by proton and carbon-13 resonance in collaboration with Bruno Hilti of Ciba-Geigy AG also turned out to be more difficult than we had thought.^{164,165} Firstly, it was difficult to obtain sufficiently large single crystals, and secondly, their conductivity led to disastrous arcing.

Two focal points characterize our more recent solid state NMR research under the guidance of Beat H. Meier: hydrogen-bond dynamics in carboxylic acid dimers,^{166–174} and the investigation of spin diffusion in disordered solids combined with theoretical considerations about spin order transfer.^{174–188}

Figure 11 (a) Group photograph of present and many former co-workers at the Nobel Prize Symposium, March 1992, Centro Stefano Francini, Ascona, Switzerland. The persons, numbered in sketch (b), can be identified from the following list. 1 Nagayama, Kuniaki 2 Wokaun, Alexander 3 Jeener, Jean; Prof. (guest) 4 Ernst, Richard R. 5 Robyr, Pierre 6 Aue, Walter 7 Macura, Slobodan 8 Blackledge, Martin 9 Müller, Irène 10 Klein, Jeannette 11 Bodenhausen, Geoffrey 12 Schaffhauser, Thierry 13 Meier, Beat H. 14 Rance, Mark 15 Kessler, Horst; Prof. (guest) 16 Müller, Luciano 17 Griesinger, Christian 18 Gemperle, Claudius 19 Schweiger, Arthur 20 Sierra, Gustavo 21 Brüschweiler, Rafael 22 Höhener, Alfred 23 Mádi, Zoltan 24 Schulte-Herbrüggen, Thomas 25 Kumar, Anil 26 Reinhold, Michael 27 Signer, Paul 28 Pastore, Annalisa 29 Bachmann, Peter 30 Schäublin, Stefan 31 Wacker, Thomas 32 Linder, Max 33 Sebbach, Jochen 34 Kreis, Roland 35 Counsell, Christopher 36 Schmidt, Jürgen 37 Boentges, Serge 38 Baumann, Thomas 39 McCoy, Mark 40 Radloff, Christian 41 Schick, Martin 42 Kogler, Herbert 43 Xu, Ping 44 Müri, Marcel 45 Xi-Li, Wu 46 Levante, Tilo 47 Welti, Dieter 48 Forrer, Jörg 49 Karhan, Jiri 50 Sørensen, Ole W. 51 Müller, Norbert 52 Schönenberger, Christian 53 Levitt, Malcolm H. 54 Zhang, Shanmin 55 Baldus, Marc 56 Stöckli, Armin 57 Meier, Beat U. 58 Suter, Dieter

Our interest in the dynamics of hydrogen bonds has been spurred by Federico Graf who joined our group in 1979 after completing a Ph.D. in EPR with Hans H. Günthard and a postdoctoral period at IBM San Jose. We wanted to gain more insight into the proton transfer dynamics in a simple double-minimum system and in the contribution of tunneling to the dissipative transfer. The experimental NMR and neutron-diffraction measurements are associated with Beat H. Meier, first in his thesis work from 1978–84;^{166–169, 189} and later through his supervision of the work of Armin Stöckli^{170, 172} and Pierre Robyr.¹⁷⁴ Of great importance to the success of this project was the support given by Rolf Meyer,^{171–173} one of the unrivalled experts in the computation and analysis of intramolecular dynamics,¹⁹⁰ as well as the support by Albert Furrer, Peter Fischer and their team regarding the use of neutron diffraction.^{167–170} Hydrogen-bond dynamics turned out to be a critical test case for our understanding of nuclear spin relaxation in solids.

The transfer of spin order through the network of dipolar interactions appeared to us to be one of the most important, interesting, and useful features of NMR in solids. Being a typical many-body problem, it is difficult to treat theoretically. Attempts in this direction have been made by Dieter Suter^{175, 178} and Malcolm H. Levitt¹⁷⁹ in our group. On the other hand, spin diffusion has turned out to be an ideal tool for studying local order in macroscopically disordered materials, such as polymers, polymer blends, and glasses. After some initial demonstration examples treated by Pablo Caravatti, Janos A. Deli, and Geoffrey Bodenhausen,¹⁷⁶ the work of Pablo Caravatti (thesis 1981–86) concentrated on polymer blends investigated by proton spin diffusion^{177, 191} in collaboration with the polymer expert Peter Neuenschwander.

The limited achievable resolution of proton resonance was soon recognized to be a grave drawback, and the desire to use carbon-13 instead was only logical. However, in natural abundance ¹³C spin diffusion can be exceedingly slow and isotopic enrichment is not always possible. This motivated Beat H. Meier to start an extensive program on techniques to accelerate spin diffusion for dilute spin systems. Thanks to his and his co-workers' efforts, we have today several possibilities in hand to increase the spin-diffusion rate, such as rotor-driven spin diffusion as developed by Marco G. Colombo and Thomas Burmeister,^{180, 181} radiofrequency-driven spin diffusion as explored by Pierre Robyr,¹⁸² and the use of xenon-129 probes as investigated by Marco Tomaselli.¹⁸⁶

The question of the reversibility of spin-diffusion dynamics has been addressed by Shanmin Zhang.¹⁸³ He has also proposed indirect measurement techniques for spin diffusion.^{184, 185} This work on spin dynamics has been well summarized and extended in a recent review by Beat H. Meier (in press).

Finally, a short but exciting excursion in the lowlands of zero-field resonance should also be mentioned. Following the footsteps of Alex Pines and his team,^{192, 193} Roland Kreis and Albert Thomas have further explored the possibilities of this fascinating technique.^{194, 195}

CONCLUSIONS

To be honest, we have made a living not only by borrowing clever ideas. Particularly in the later phases, numerous new concepts have been created in-house by a number of incredibly

gifted co-workers. Thus our research group has been lucky in two respects, the influx of brilliant ideas and of even more brilliant individuals (Figure 11).

This essay certainly provides a one-sided view of NMR history. Because of lack of space, it is impossible to do justice to all former co-workers and even less to other research groups.

Farrar, Thomas C.: Historical Reminiscences of Some NMR Experiences

Thomas C. Farrar

University of Wisconsin, Madison, WI, USA

I arrived in Urbana, Illinois on 21 August 1954, a naive young man from the dusty plains of Wichita, Kansas. I had decided to work for Professor Herbert S. Gutowsky even before I left Wichita. A neighbor, David McCall, had recently finished his Ph.D. work with Professor Gutowsky and he told me and some of my other undergraduate colleagues about what an absolutely splendid fellow Gutowsky was and how this new field of research in nuclear magnetic resonance was truly going to revolutionize chemistry. I have often wondered if he realized back in 1953 how true his prophesy would be!

On arriving in Urbana, I was a bit disappointed to learn that Herb was away on sabbatical leave and did not plan on returning until the summer of 1955. But, as is usually the case with beginning graduate students, I was so busy taking classes and teaching in the first two semesters that I had very little time for research. I dutifully took the suggested classes and scheduled interviews with all members of the Physical Chemistry Division and remained firm in my wish to work in this new field of NMR spectroscopy. Herb returned in the late spring of 1955 and I had my first taste of real NMR research in the summer of 1955.

There were so many things happening in those early days that it is difficult, 40 years later, to remember the exact chronology. It is quite easy to remember, however, one of the initiation rites of new Gutowsky graduate students, the task of mapping the field of the permanent magnets and using a piece of fine emery paper to sand down the high spots in the pole faces in order to obtain a more homogeneous magnetic field. Since the magnet pole faces all had a sharp, raised, outer circumference, the task of pole face polishing usually resulted in a case of badly skinned knuckles. New Gutowsky graduate students were easy to spot because they were the ones that went around for the first month or two with Band-Aids on all or most of their knuckles. That first summer was also interesting because Herb had received a very nice package in the mail from Rex Richards, who at that time was Professor of Physical Chemistry at Oxford. In the package were two beautiful pieces of embroidery. The embroidered art-work consisted of two circular pieces of silk, each about 8 in. in diameter. In the central part of the circles was a rather complex pattern, sewn with fine copper wire. The patterns were designed in accord with some calculations which had recently been completed by Marcel Golay. The idea was that if one placed these embroidered circles on the pole faces of the magnet and then put the proper amounts of current through the various copper patterns, this would result in a magnetic field of greatly improved homogeneity. The silk circles were mounted on the magnet pole faces in the prescribed manner and the loose pieces of fine copper were attached to some simple variable current power supplies. Several of the members of our research group then tried for a week or two to improve

the magnetic field using these early shim coils. In the end we gave up and went back to skinned knuckles!

Several months after this unsuccessful effort to use shim coils, we tried another new idea which had been received from the West Coast. Bloch had tried to stir an NMR sample in order to average out magnetic field inhomogeneities. This did not work very well, but Wes Anderson then came up with the idea of rotating the NMR sample tube and this worked very well indeed. The radial magnetic field inhomogeneities were averaged and the sharpness of the spectral lines was greatly improved. This idea we tried and for us, too, it worked very well. This was a really very important step forward because sensitivity and resolution in those days were not very impressive.

There were two permanent magnets used in the Gutowsky group at that time, and a year later a commercial electromagnet was added. The larger permanent magnet had a pole face diameter of about 8 in. and a field strength of about 0.7 T (a proton resonance frequency of about 28 MHz) and was used primarily for wide-line studies of solids and polymer samples. The smaller one had a pole face diameter of about 6 in. (as I recall) and a magnetic field strength of about 0.5 T (a proton frequency of about 17.5 MHz); it had much better homogeneity than its larger brother. The smaller magnet was used for high-resolution studies. The high-resolution spectrometer itself was essentially a radiofrequency (rf) bridge with the sample being placed in the coils which served as the inductance in a tuned circuit of one part of the bridge. As the magnetic field was swept and a resonance condition was reached for some particular group of protons they absorbed energy. This caused the bridge to become unbalanced and the relative degree of unbalance was proportional to the relative number of protons at resonance.

The spectra were recorded on a Sanborn recorder which had a very fast response (these Sanborn recorders were the same ones that were frequently used in a number of early medical instruments), but resulted in spectra which came out on curly rolls about 15 in. long and 3 in. high. The paper used on these rolls was designed in such a way that lying flat was a very high energy configuration; the low energy configuration was to curl up into a tight roll. The rf bridge consisted of a rat's nest of wires, capacitors, resistors, and inductors, all of which were stuffed into an old shoe box. Of course, the shoe boxes made 40 years ago were very substantial and sturdy, not the flimsy affairs which are used these days. The lid of a metal coffee can, which was about 7 in. in diameter, was attached to the shaft of the tuning capacitor in order to allow more precise tuning of the rf bridge. Although the spectrometer looked rather crude it often out-performed the new 40 MHz commercial spectrometer which had been recently installed down the hall in the Noyes Laboratory.

Spectral resolution was always a problem in those early days. One very frustrating problem was that good homogeneity was a bit like the weather. It often changed from good to bad rather abruptly and was rather unpredictable. At one point a large box was constructed (not out of the usual cardboard, but out of sheets of very substantial 3/4-in. plywood) and placed around the high-resolution magnet, its temperature being controlled as precisely as was possible in those days. When the magnet was in good form and the homogeneity was really outstanding, samples were run as rapidly as possible and

students often worked around the clock in order to get their spectra before the homogeneity took a turn for the worse.

Gutowsky's research group was quite large in the early days (17 to 20 people) and there were three major areas of research, wide-line studies of solids and polymers, high-resolution NMR (both experimental and theoretical), and pulsed NMR work (both experimental and theoretical). The theoretical work was rather interesting since much of it involved the use of the Illiac computer. This machine was really awesome. In those days, of course, one had only vacuum tubes. The heat output of the Illiac was, as I recall, about 50 kW! It had 1024 words of memory and each word consisted of 40 binary bits. There was no floating point arithmetic available and all calculations had to be scaled such that no number was greater than one. Addressing was also fixed, so great care was needed if a program had to be modified by adding an additional instruction or an additional piece of data. Input was via punched paper tape and all programming was in machine language, i.e. hexadecimal numbers. Access to the computer was via debug sessions each morning and each afternoon. No more than about 5 min per person was allowed for the debug sessions. Even with all the difficulties, however, the Illiac could do an awesome amount of calculating once a program was up and running.

One of the problems I worked on at Urbana had to do with the measurement of the proton-proton spin coupling constant in methane. The problem I had really started to work on was an experimental test of some calculations which had been done by Ed Stejskal on the rotational energy barrier of the methyl group in methylchloroform. I thought I might try to make d_1 -methylchloroform, since Ed's theory predicted that its barrier should be quite different from isotopically normal methylchloroform and we might be able to distinguish the difference between a tunneling model and an activation model. My copy of 'Organic Chemistry' by Fieser and Fieser indicated that if one added DCl to vinyl chloride, the result should be d_1 -methylchloroform. The synthesis seemed to work as indicated and in order to check the purity we decided to look at the high-resolution proton NMR spectrum. Much to our surprise we got quite a mixture of compounds ranging from no deuteration to d_3 -methylchloroform. We were also delighted to observe that we had obtained the proton-deuteron spin coupling constant, which was about 1.7 Hz, indicating that the proton-proton spin coupling constant was about 12 Hz. This was most interesting because a recent molecular orbital calculation on methane came up with the result of about 200 Hz. We didn't really think that the difference between methylchloroform and methane could be so great, but I decided to synthesize d_1 -methane anyway. Again, the proton-deuteron coupling constant was found to be about 1.7 Hz. This was the beginning of a long and productive collaboration with Martin Karplus on the calculation of spin-spin coupling constants. But that is another story.

Another interesting observation about the proton spectrum in the methane sample (which was a gas at about 10 atm pressure in a 5-mm NMR tube; boy did we love to live dangerously in the old days!) was that the lines were rather broad. We had a number of interesting theories about the reason for the broad lines, including one which postulated that since the sample was gaseous perhaps the gas molecules remained stationary as the sample tube was spun. We even constructed an NMR tube with glass partitions to ensure

that the gas molecules were being averaged over the radial field inhomogeneities; this helped not a bit. It was not until several years and many experiments later that other members of Gutowsky's group tumbled to the fact that spin rotation relaxation caused the relaxation times to be very short, which in turn led to the broad lines.

In about my last year in Urbana, Martin Karplus got the great idea that I should go to Cambridge to work with Frank Boys who had come up with a brilliant new way of calculating the multicenter integrals which are required in *ab initio* quantum mechanical calculations. I was fortunate enough to be awarded an NSF postdoctoral fellowship and did go to Cambridge to work with S. F. Boys. When I arrived in Cambridge, Professor Longuet-Higgins tried very hard to convince me that working with Dr. Boys was a terrible mistake and a waste of time. I did some work with Longuet-Higgins, but then decided that working with Dr. Boys would be more interesting and challenging. I was involved with him and members of his research group in the development of Gaussian-59. The calculations were done on the Edsac-2 computer. It had 1024 words of 40-bit memory (RAM) and an additional 1024 words of stored programs (ROM). Both Edsac-2 and the Illiac were designed by David Wheeler, but the Edsac had a large number of advances over the Illiac. Edsac-2 had floating point arithmetic and address modifier registers. And, most importantly, it had four magnetic tape drives for storing overlay programs and data. One of the first molecules we studied when the programs were finally all up and working properly was N_2 . It took about 30 min to do the calculation; it had taken Daniel Kaestler (a graduate student with Roothaan at the University of Chicago) several years to calculate the same integrals by hand! Unfortunately, it would be many years before computer hardware was advanced enough to carry out accurate calculations of chemical shift tensors and other interesting NMR parameters.

After a brief go at academia in Eugene, Oregon, I accepted a job at the National Bureau of Standards in Washington, D.C. Since pulse NMR spectrometers were not available in 1963, we decided to have one built at NBS. After about a year the electronics shop delivered to us a spectrometer, but it didn't work. So, armed with a copy of the bible according to the AARRL (The American Amateur Radio Relay League), we set to work fixing the problems. Much of the early work was concerned with relaxation time measurements in liquids and solids. During some of the lectures that Ted Becker and I were giving at an NIH continuing education course, Gitte Vold suggested that we try some Carr-Purcell experiments to measure chemical exchange rates. That sounded like a great idea, but by the time we had improved the sensitivity and the stability of the spectrometer to the point that we could make meaningful T_2 measurements, we realized that it was also stable enough to obtain good pulse high-resolution FID (free induction decay) signals. The spectrometer was an eclectic mixture of new and old, the old being the external fluorine lock which used an rf bridge very similar to the one used by Bloembergen, Purcell, and Pound. This led us into the area of high-resolution pulse NMR spectroscopy.

At a meeting of the Society for Applied Spectroscopy in Anaheim, California (Disneyland) in 1970, we showed some of the first carbon-13 FT NMR spectra. Tony Keller was also at the meeting and he too had just obtained some nice ^{13}C FT NMR spectra. The improvements in sensitivity for ^{13}C

were so impressive that everyone was very keen to start doing such experiments. The collaborative work between NIH (Ted Becker and his group) and NBS (my research group) used our homemade spectrometer and a Fabri-Tek model 1064 signal averager. The 1064 had 4096 words of 20-bit memory and the output was in the form of punched paper tape. FID spectra were output on the punch paper tape and when we had a laundry basket full of tape we would drive 10 miles down the road to NIH to carry out the data reduction. The data reduction at NIH involved several computers since the computer which could read the punched paper tape had no plotter or graphics; it was used to convert the paper tape to punched cards which were then carried to another computer where the Fourier transformation and plotting were done. After a year of this tedious process we convinced Dick Cushing of Fabri-Tek (which later became Nicolet Instruments) to build a very simple computer into the signal averager. My group at NBS purchased model #1. It worked beautifully from the first day it was installed and was still working a few years ago. Dave VanderHart tells me that it is no longer being used. One of the early attempts to improve sensitivity involved pulse sequences similar to those now used in DEPT and other experiments. We called our experiment the DEFT experiment (driven equilibrium Fourier transform). We had originally thought about calling it the LEFT (longitudinal equilibrium Fourier transform), but the McCarthy days were still fresh in everyone's mind and the US government was not wildly enthusiastic about LEFTist activities.

Those were wonderful years in Urbana and in Washington. There are wonderful memories of the excitement of many new discoveries and of stimulating, challenging, and productive seminars and discussions with Charlie Slichter and the members of his research group, who were just across the street in the physics building. What really amazes me is the rate at which new experiments and new discoveries continue to be made in the field of NMR spectroscopy. Dave McCall was indeed correct; NMR has very much changed forever the field of chemistry.

Thomas C. Farrar. *b* 1933. B.Sc., 1954, Chemistry and Mathematics, Wichita State University, Ph.D., 1959, Physical Chemistry, University of Illinois-Urbana, (Supervisors H. S. Gutowsky and Martin Karplus). NSF Postdoctoral fellowship in theoretical chemistry, Cambridge University, UK (with S. F. Boys) 1959–61. Assistant Professor of Chemistry, University of Oregon-Eugene, 1961–63. National Bureau of Standards, 1963–71 (Chief of Magnetism Section). JEOL, Ltd. Director of Research and Development, 1971–75. National Science Foundation, Director of Chemistry Instrumentation Program, 1975–79. University of Wisconsin, Professor of Chemistry, 1979–present. Research interests include high-resolution, pulse and solid state NMR spectroscopy, study of structure and dynamics in liquids, hydrogen bonding, NMR relaxation time theory and experiments.

Feeney, James: Personal Reminiscences on NMR

James Feeney

National Institute for Medical Research, London, UK

In July 1957 I received a letter from Les Sutcliffe explaining that I had been allocated to work with him during the final year of my chemistry degree course at Liverpool University. He wrote 'I have decided that your research problem will be in nuclear magnetic resonance spectroscopy. This is an excellent opportunity because this subject is one of the newest and most promising in Chemistry'. What a prophetic statement and what amazing good fortune for me! Earlier that year, Les Sutcliffe had taken delivery of one of the first NMR commercial spectrometers in the UK, a 40 MHz Varian instrument. By the time I arrived he had already decided that the original purpose for which it was bought, namely to support his ongoing studies on metal redox reactions, was not going to be feasible at the low sensitivity available and that studies of molecular conformations in fluorinated molecules via ^{19}F NMR would be a much more fruitful area. Looking back on those days, I recall that a great deal of time was spent on 'finding resonance' (the electromagnet was usually switched off overnight) and then searching for homogeneity 'hot-spots' in the field to give good resolution. Occasionally, when everything was just right, we would record superb spectra on our compounds which almost always revealed something new and interesting! Much time was spent on constructing and testing 'home-built' variable temperature units and probes for the conformational work. During these studies we detected and characterized the large geminal F, F coupling constant (~ 290 Hz) and other longer range couplings in fluorinated cyclohexanes.¹ In those days it was fashionable to carry out detailed spectral analysis on second-order spectra and our compounds provided many such examples (for example, SF_5X compounds were analyzed with Jim Emsley and Neville Boden as AB_4 spin systems).²

In January 1961 I met Warren Proctor at a conference in Bradford (my first public NMR lecture) and I like to think that this chance meeting subsequently led to my joining Varian in 1964. Those Varian days were exciting with excellent equipment and stimulating colleagues, such as Jim Shoolery, Leroy Johnson, and Attilio Melera. I can still remember visits to the laboratory by eminent organic chemists reexamining compounds they had synthesized, sometimes 20 years earlier, and being amazed at the structural details revealed by the new NMR technology. At that time, the application of double and triple resonance and early NOE measurements, mainly on the HA-100, were all part of the 'modern' approach to structural NMR work. One of our experiments, dating from 1969, showed that gated double resonance could be used to enhance the sensitivity of nondecoupled ^{13}C spectra by retaining $\{^1\text{H}\}^{13}\text{C}$ NOE information after the decoupler was switched off;³ this was the forerunner of many variations of such gated decoupling experiments.

During my time at Varian I became increasingly aware of the potential use of NMR in biology—stimulated largely during visits by Arnold Burgen. He was convinced of the powerful role that NMR would eventually play in monitoring

protein–ligand interactions. In 1970 I eventually joined Arnold Burgen and his colleagues (Jim Metcalfe, Gordon Roberts and, later, Berry Birdsall) in his newly established MRC Molecular Pharmacology Unit in Cambridge, which later transferred to the National Institute for Medical Research at Mill Hill. In the early days we managed to get useful information by concentrating on NMR studies of isotopically labeled ligands bound to proteins. These studies allowed us to characterize the multiple conformational states that frequently exist in protein–ligand complexes and also the dynamic processes involved in the protein–ligand interactions during the lifetime of the complex. Some of our experiments have proved to be of general use. For example, in 1974 (with Poul Hansen) we found that the $\beta\text{-CH}_2$ protons in peptides could be assigned stereospecifically and rotamer populations determined by considering both $^3J(\text{H,H})$ and $^3J(\text{C,H})$ coupling constants.^{4,5} In another experiment we drew attention to the potential of NOE difference spectroscopy and showed how this could be used to follow pseudo INDOR effects (1973).⁶ Our initial protein ^1H NMR experiments were at 100 MHz on proteins such as dihydrofolate reductase (M.W. 18 300) and these yielded very few assigned signals. Of course, nowadays, modern 2D and 3D experiments on the isotopically labeled protein at 600 MHz give us essentially all the resonance assignments. In the late 1970s, during some magnetization transfer experiments, we were surprised to observe negative intramolecular NOE effects between protons in a free ligand examined in the presence of its protein–ligand complex (with Jean Pierre Albrand). These NOE effects were transferred to the free ligand by exchange between the bound and free species and allowed us to obtain the conformation of the bound ligand from NOE observations on the free ligand.⁷ We also participated in the search for solvent suppression methods and suggested the use of data shift accumulation methods for overcoming the dynamic range problem (in 1979 with Klaus Roth and Barry Kimber).⁸

The phenomenal progress in protein structure determination using NMR has ensured that the promise predicted for the technique by the early workers has been fully realized and there is no doubt that activity in this area will continue to expand.

James Feeney. *b* 1936. B.Sc., (Chemistry), Ph.D., (supervisor Les Sutcliffe), D.Sc., University of Liverpool. Lecturer in Chemistry, University of Liverpool, 1961–64. Varian Associates 1964–69 (final position, Director, European Laboratories). 1969–present, British

Medical Research Council (Cambridge 1969–72, National Institute for Medical Research, Mill Hill, 1972–present). Currently Centre Controller, MRC Biomedical NMR Centre and Head, Laboratory of Molecular Structure, NIMR. Visiting Professor at University of Surrey since 1985. Approx. 250 publications. Research interest: NMR studies of protein–ligand interactions.

Ferguson, Raymond C.: William D. Phillips and Nuclear Magnetic Resonance Spectroscopy at DuPont

Raymond C. Ferguson

Formerly Central Research Department, E. I. duPont de Nemours & Co., Wilmington, DE, USA

This article was originally assigned to Bill Phillips, but he had only completed the following before his death in 1993:

In 1951 I completed requirements for my Ph.D. in Physical Chemistry at the Massachusetts Institute of Technology (MIT) and accepted an offer of employment at the Corporate Research Laboratory of DuPont in Wilmington, DE. My thesis work had been in the area of vibrational spectroscopy (infrared and Raman) and, although I was never again to utilize seriously this powerful tool in research, vibrational spectroscopy with its group frequencies and symmetry-based selection rules provided a basis (emotional as well as technical) for entry into the relatively virgin territory of NMR of molecules in late 1953. My first victory in NMR came with the assignment of the two AB doublets in the ^{19}F spectra of a series of substituted tetrafluorocyclobutanes that had been submitted to Varian Associates in the course of negotiations between Varian and DuPont for the purchase of a spectrometer.

In due course, a Varian 30-MHz spectrometer was delivered to Wilmington in early 1954. Unfortunately, the magnet had been shipped with water left in the magnet cooling coils. In trucking the magnet from Palo Alto, CA, to Wilmington, the water in the cooling coils had frozen, expanded, and left the magnet totally inoperable. In short order, however, the magnet was replaced, the rf unit was upgraded to 40 MHz, and provision was made for sample spinning. By mid-1954, we had a functioning NMR spectrometer capable of obtaining ^1H and ^{19}F spectra at 40 MHz.

I first met Phillips in 1954, but was not directly involved with his work until 1964. I did, of course, follow his work closely, and occasionally met with him to discuss problems of mutual interest. Phillips was always an enthusiastic promoter of NMR and other spectroscopic and physical methods. He was always helpful to me and others who were working in these fields.

In this article, I review his contributions, guided by his own summary of major scientific contributions, written earlier. I have added discussion of my own work. The time period covered is from 1953 to the mid-1970s. Neither of us was directly involved in NMR at DuPont thereafter. Space limitations make it impossible to discuss the work of other colleagues in various departments at DuPont, many of which were significant.

The Central Research (then Chemical) Department of DuPont was the first industrial laboratory to acquire a

high-resolution NMR spectrometer. Howard S. Jarrett had been doing EPR with a Varian Associates spectrometer. His supervisor, Monroe Sadler, learned of the NMR development and visited Varian to get more information, and provided samples for study. DuPont ordered a spectrometer.

Phillips (I am told) reluctantly agreed to take charge of the work, with the promise that he would not have to get bogged down with electronics problems (he always wanted to concentrate on fundamental physical chemistry, and was aware of the electrical problems Jarrett had encountered in his work).

However, this assignment worked out well. His wife, Esther, has told me that the early days in NMR were the most exciting of his career, and I would say, also of my own. My wife referred to 'my' first NMR spectrometer as 'his new toy'. Everything we did then was new, unique, and exciting.

Phillips was clearly a pioneer in the application of NMR to the structural, dynamic, and electronic properties of molecules. While at DuPont he published nearly 70 papers, mostly on high-resolution NMR, but also using ESR, IR, and other methods. He continued NMR work as he advanced in research management. His first DuPont paper confirmed restricted rotation in amides¹ and the last was a biochemical paper on the mechanism and kinetics of allene reduction by *Azotobacter* nitrogenase.²

The large chemical shift dispersion of ^{19}F NMR resonances and substantial research programs in fluorine chemistry at DuPont made fluorine work particularly attractive, and led to significant early discoveries, particularly involving the stereochemistry and analysis of spin-spin splitting patterns.

Phillips continued the ^{19}F work on tetrafluorocyclobutanes which had been started at Varian. He published spectra, chemical shifts, and spin-spin (J) coupling constants of a series of 17 tetrafluorocyclobutanes substituted unsymmetrically with respect to the plane of the cyclobutane ring.³

Nonequivalence of the two fluorines bonded to a common ring carbon atom produced four-line patterns which were not the expected pair of doublets separated by the chemical shift difference. This may have been the first recognized example of 'strong coupling'. Phillips introduced the appropriate AB spin system analysis, which continued to be important in continuing work on asymmetric systems.

Another major contribution was the earliest application of NMR to studies of hindered rotation in organic molecules.⁴ He confirmed hindered internal rotation about the C-N bond in amides, which had been postulated, but never before confirmed experimentally.¹ He mentioned the significance of this result with respect to the structures of protein molecules, perhaps anticipating his later interests.

Due to conjugation of the double bond, *N,N*-dimethyl formamide, $(\text{CH}_3)_2\text{N}-\text{C}=\text{O}$, has a nearly planar structure which places the methyl groups in magnetically nonequivalent environments. He observed two methyl resonances in the ^1H spectra. Temperature dependence and coalescence of the methyl resonances at elevated temperatures allowed estimation of the rotational barriers.

Proton NMR and infrared work on a series of nine nitrosoamines, $\text{R}'\text{R}''\text{N}-\text{N}=\text{O}$, demonstrated nearly planar structures and temperature dependence due to restricted internal rotation around the N-N bond. Similar work on six alkyl nitrites, $\text{R}-\text{O}-\text{N}=\text{O}$, revealed restricted rotation around the N-O bond.

The effects of asymmetry were further demonstrated by ^{19}F NMR evidence of restricted rotation about the C–C bond in four substituted *gem*-difluoroethanes.⁵ Absolute rotational configurations were assigned on the basis of spin–spin splittings and temperature dependencies of the spectra.

Early on, Phillips recruited Harlan Foster, an experienced organic chemist, to take over the increasing demand for ‘service work’, mainly organic structure analysis. Foster became one of the finest practitioners of that art that I know of.

This was a clever move by Phillips, because he was then able to be more selective in his own research, and to branch into other forms of spectroscopy and physics. He became head of a group working on special projects using NMR, ESR, Raman, infrared spectroscopies, and other physical methods.

He and Earl L. Muetterties used ^{19}F in studies of structures and fluorine-exchange processes in inorganic fluorides of the type MF_n , where $n = 3, 4, 5, 6$, such as SF_4 , ClF_3 , and fluoroarsenates.⁶

He investigated other nuclei, most successfully ^{11}B . He and his co-workers reported the ^{11}B chemical shifts and ^{11}B – ^1H J coupling constants for 30-odd representative examples of boron-containing compounds.⁷ Conclusions regarding bonding were made and temperature dependence studies undertaken on selected samples. This and other work on organo-inorganic and organometallic systems in cooperation with Muetterties and others produced significant and useful results for research efforts at DuPont.

The discovery of an apparently anomalous effect of paramagnetic ions on the magnetic resonance absorption of alcohols⁸ led Phillips later to use paramagnetic ions to elucidate the structural and electronic properties of transition metal chelates and of paramagnetic proteins such as cytochrome-*c* and plant and bacterial ferredoxins.

In a series of papers beginning in 1960, he and co-workers used isotropic contact proton hyperfine interactions to determine the configurations and magnetic properties of paramagnetic bis-nickel(II) chelates of aminotropones.⁸ Spin densities from Ni transmitted through N, O and S atoms connecting conjugated ligands produced large high- and low-frequency chemical shifts of the protons on the ligands. Synthesis and study of compounds with various ligands allowed the determination of spin densities of a large number of aromatic, cyclic 7-carbon, alkyl, and fluorine substituents.⁹ Similar studies were made on nickel(II) salicylaldimines.

In the late 1950s, Phillips realized that modern physical methods had great potential for biological research, and a future for chemical and physical research and development in the chemical industry. He took leave of absence to go to MIT for postdoctoral work in biochemistry for the academic year 1962–63.

This was a significant break from his early emphasis on fundamental electronic and structural properties of inorganic, organic, and organometallic compounds. He published around 30 papers, mostly NMR and ESR, on the earlier work. Collaborators who made significant contributions included J. J. Drysdale, C. E. Looney, E. L. Muetterties, H. C. Miller, H. Foster, D. B. Chesnut, R. E. Benson, D. R. Eaton, D. R. Josey, and R. E. Merrifield.

In the meantime, other DuPont research laboratories were moving into NMR. I first heard about nuclear induction or nuclear magnetic resonance while at Harvard University

in 1950–53. Daniel Kivelson, a fellow graduate student in chemistry, gave a seminar about the Purcell and Pound work. He covered their broadline work on solids, including natural rubber and gypsum. I do not recall any mention of high-resolution work on liquids.

When I joined DuPont at the Jackson Laboratory, Organic Chemicals Department in 1953, I was assigned to a group developing synthetic polyurethane elastomers for which my thesis on gas-phase microwave spectroscopy was not helpful. William Remington, my division head, discussed the Purcell and Pound paper with me, but questioned their interpretation of the effects of sulfur curing on natural rubber. We were both unaware of any high-resolution work and agreed that NMR would probably not be helpful to us.

However, Rudolph Pariser, my group leader, had better information and a more optimistic view. He sent me to see Phillips, who acquainted me with high-resolution NMR on liquids and solutions, illustrated with his results on organic compounds

I became a believer and helped prepare a project proposal to acquire our own NMR spectrometer. The proposal was rejected, partly because the largely organic and dye chemistry management was not quite sure about physical chemists, and perhaps more importantly, about unproved expensive instrumentation. They, and perhaps we, did not fully appreciate the revolutionary impact NMR and other developing instrumental methods would have on organic chemistry.

Nevertheless, I was assigned liaison with Phillips and provided him with research samples of mutual interest, including some polymers. The first was poly(tetramethylene ether glycol), a component of our polyurethane elastomer. This was a viscous liquid of about 1000 molecular weight which we were able to run neat. We observed two methylene and a hydroxyl resonance with unresolved fine structure. A few weeks later, Phillips repeated a scan of the sample and found changes in the pattern, which we learned were due to oxidative degradation. Sample stability was then, and forever, a problem. It was an indication of Phillips’s alertness to any unusual result that he immediately called me.

Shortly after our unsuccessful proposal to acquire an NMR spectrometer, John D. Roberts (MIT) and Melvin Calvin (University of California), highly regarded consultants, visited Jackson Laboratory within a week or two of each other. They persuaded our management that NMR had great potential for support of organic chemistry, which was the major focus of Jackson Laboratory research. The directors then asked for a proposal which Remington and Pariser submitted, diplomatically failing to mention the earlier one.

I am reliably informed that Roberts was introduced to Phillips at DuPont, and that Phillips introduced Roberts to high-resolution NMR. At any rate, Roberts continued as a consultant and I saw him frequently. I often felt that we taught him more than we learned, but the relationship was symbiotic. He was very helpful in keeping us and our managements informed about significant developments in NMR in the outside world, and went to bat on our behalf with our managements.

Jackson Laboratory acquired a 40-MHz spectrometer equipped for ^1H , ^{19}F , and ^{13}C in late 1954 or early 1955. Our riggers dropped the magnet, fortunately on the yoke, so the only significant damage was to the floor. I have heard that

Varian had many other difficulties in getting their electromagnets delivered safely.

The original Varian 30- and 40-MHz spectrometers were electromagnet/continuous wave (CW) radiofrequency (rf) systems and had no field/frequency control. Spectra were recorded by sweeping the magnetic field. The systems were so unstable that spectra could only be observed by rapid scan oscilloscope display or recorded on a fast-writing Sanborn recorder. Tuning for resolution and examining multiplet structure were done mainly on the oscilloscope. We were usually able to distinguish singlets, doublets, triplets, quartets, and 'multiplets'. External magnetic perturbations were a serious problem, and made plumbers, construction workers, delivery carts, and swining metal doors enemies of progress.

Varian developed a 'Superstabilizer' which sensed the magnetic field through pick-up coils around the magnet poles, and used an optical galvanometer feedback system to correct the fluctuations. This was a significant improvement. Later, the development of field/frequency lock on the line of an internal reference compound was an even better solution.

With the acquisition of our own instrument, I began providing service work at Jackson Laboratory, mainly for structural analysis and purity estimations on organic compositions, including fluorocarbons and fluoropolymers. In those days, with fixed rf frequency, we had to change the magnetic field to study other nuclei. Thus, most of the early work was done on proton resonance.

Some of my work involved interesting proton spectra of substituted tetrahydrofurans, with one or more alkyl groups attached to the $(\text{CH}_2\text{CH}_2)_2\text{O}$ ring. Asymmetric substitution across the plane produced nonequivalence of the sets of methylene protons and complex spectra such as observed for the tetrafluorocyclobutanes. In addition, the samples were often mixtures, making the analysis more difficult. I spent considerable time on this work, until the head of the synthesis group found out that my NMR charges were breaking his budget. We were, however, able to identify the structures and estimate purities — work that would have been difficult, costly, or impossible by conventional characterization methods.

The ^{19}F work was exciting because of the large chemical shift range and magnetic inequivalence effects, such as those seen by Phillips. My first NMR paper was on the compositional and structural analysis of vinylidene fluoride/hexafluoropropylene copolymers with a range of mole ratios.¹⁰ The 40-MHz ^{19}F NMR spectra had resolved patterns for four basic sequences, $\text{CH}_2\text{CF}_2\text{CF}_2\text{CF}(\text{CF}_3)-$, $-\text{CH}_2\text{CF}_2\text{CF}(\text{CF}_3)\text{CF}-$, $-\text{CH}_2\text{CF}_2\text{CH}_2\text{CF}_2-$, and $-\text{CH}_2\text{CF}_2\text{CF}_2\text{CH}_2-$. The mole ratios of the monomers and the fractions of the above sequences could be determined from intensity measurements. There were no hexafluoropropylene-hexafluoropropylene dyads, consistent with the inability to homopolymerize this monomer or to incorporate it in the copolymers at greater than 50% molar concentration.

In 1958 I was assigned to the Elastomer Chemicals Department and moved into other projects. In 1960 we moved to a new laboratory at the experimental station, and I was assigned to the infrared laboratory and to liaison for NMR work being done for us in the Central Research Department. They had by then, or shortly thereafter, acquired a Varian spectrometer operating at 100 MHz for protons and 94.1 MHz for fluorine.

We acquired a Varian A-60 spectrometer and I began work on monomers and polymers. The NMR spectrum of an all-*cis*-polychloroprene prepared by a stereospecific route confirmed the *cis* structure. Additional studies of typical free radical-initiated polychloroprenes (neoprenes) revealed greater structural complexity than had been known previously.¹¹

Chloroprene, $\text{CH}_2=\text{CCl}-\text{CH}=\text{CH}_2$, typically polymerizes mainly 1,4 to produce *cis*- and *trans*-2-chloro-2-butyldiene-1,4- $-\text{CH}_2-\text{CCl}=\text{CH}-\text{CH}_2-$ units, and also polymerizes 1,2 and 3,4 to produce minor amounts of $-\text{CH}_2-\text{CCl}(\text{CH}=\text{CH}_2)-$ and $-\text{CH}_2-\text{CH}(\text{CCl}=\text{CH}_2)-$ units, respectively. The methylene region of the proton spectra revealed that the basic 1,4-polymerization units were attached to each other head-to-tail in about 70%–80% of the pairs, but had 15%–10% each of head-to-head and tail-to-tail attachments.

The spectra of some of the monomers and model compounds related to this work led me into computer fitting of more complicated spectra. I worked with Donald Marquardt, a mathematician/statistician in our engineering department, using their Univac computer. We chose to follow the magnetic equivalence factoring method introduced by Swalen and Reilly.¹² This was an iterative approach in which trial spectra were calculated using estimated parameters. Tentative line assignments to the observed frequencies were made, then the program produced the statistically best fit to the energy levels. These were then applied in a second step to calculate the best parameter estimates. We applied the method to the proton spectra of propane, isobutane, 4-chloro-1,2-butadiene and other compounds.^{13,14}

Perhaps my most significant contribution was in getting Marquardt involved. His statistical procedures, which later became known as the Marquardt/Levenberg algorithms (widely used in multiregression analysis), were later incorporated into more sophisticated computer programs which fit lineshapes and intensities, rather than frequencies alone.

I later wrote a program for simulating many-spin spectra, specifically designed for trial fitting of polymer spectra.¹⁵ This was applied to computer simulations of the 220 MHz spectra of polypropylene and other synthetic polymers. The basis was to input subspectra for the various stereoregular sequences, which were combined with appropriate probabilities to match the observed patterns.¹⁶

When Phillips returned to DuPont as an Assistant Director of Basic Science, he formed a research group which included a number of disciplines, including his chosen field, biophysics. NMR projects were his major interest, but because of administrative duties collaborators did most of the work. Nevertheless, he kept in close touch with the work. I learned that the best time to talk with Phillips was about 7 a.m., when he would be in his office reviewing the previous day's (or night's) NMR results, even before reading the *Wall Street Journal*.

In 1964, the maximum field strength of conventional magnet systems having been reached, Varian Associates approached DuPont with a proposal to build a 300-MHz superconducting solenoid spectrometer. Phillips was particularly interested because of difficulties in resolving the proton spectra of biopolymers at 100 MHz. I transferred to Central Research Department to take charge of the operation of this new spectrometer. Varian loaned us a 200 MHz prototype during fabrication of our spectrometer.

Because of limitations in wire technology, Varian was unable to reach the target field, and finally produced a 220-MHz ^1H spectrometer which we accepted. I came later somewhat to regret this because it was a difficult system to operate and maintain. It had a liquid helium hold time of about 48 h, which required someone to come in on weekends and/or holidays to top up the Dewars. Fortunately, we were running a two-shift operation, including weekend work by enthusiastic visiting scientists. Spectrometer time was divided between biophysics and other research, somewhat disproportionately in favor of the former.

The system was prone to spontaneous quenches (collapse of the field) and because it was difficult to establish field and resolution from a 'warm' start, we kept it at field continuously. It also had poorer resolution and worse spinning sidebands than the later 220- and 300-MHz spectrometers Varian made. Nevertheless, it was used very effectively for several years, and was only replaced when spontaneous quenches became too frequent.

With this spectrometer Phillips and his co-workers revealed the large and characteristic differences in the spectra of proteins in the reversibly denatured (biologically inactive) and the folded (biologically active) states. The differences were attributed to proximity effects (ring current shifts, hydrogen bonding, etc.) that occurred in the folded form of the protein and were absent in the unfolded form. They demonstrated that the spectra of denatured (unfolded) proteins were well represented by the sum of the individual amino acid resonances, while the proteins had significantly different spectra in their natural (folded) state.¹⁶ The differences were due to hydrogen bonding and interactions with other groups in close proximity in the folded state.

It was further demonstrated that, at the higher resonance fields provided by the superconducting solenoid, inequivalent hydrogen atoms of native proteins could be resolved and, in favorable circumstances, uniquely assigned to hydrogen atoms of the protein. These and subsequent studies provided necessary underpinning to the remarkable work of others who have developed NMR into a unique tool for the elucidation of the three-dimensional structure of proteins in solution.¹⁶

I regret that I cannot give a better account of the biopolymer work, consisting of nearly 40 papers. However these contributions have been better discussed by Jardetzky and Roberts,¹⁷ and others. Among the collaborators in the biopolymer work were C. C. McDonald, J. Lazar, J. D. Glickson, M. Poe, J. F. Weiher, R. G. Bartsch, W. Lovenberg, R. F. W. Hardy, and R. C. Burns.

In 1974 Phillips accepted a transfer to England as Technical Manager of a mycoprotein venture at The Lord Rank Research Centre. This was a joint venture with DuPont, targeted toward manufacturing synthetic food for human consumption. When DuPont dropped out of this venture he returned to Wilmington in 1976 to become an Assistant Director of Research in the Polymer Department. However, these assignments took him away from his primary interests in science, so in 1977 he went to Washington University in St. Louis, MO, and later on to other posts.

My work at the higher frequency was devoted principally to the structural analysis of synthetic polymers, including the tacticity of polypropylene and poly(methyl methacrylate), monomer sequences in copolymers, and branch and end-group studies.^{16,18}

In the mid-1970s I was assigned other work and, though I used NMR, I was not actively involved in operating the equipment. Like Phillips, I spent most of my NMR career in the CW world, mainly on proton and fluorine resonance. We were getting out just as Fourier transform NMR was opening up new applications of carbon-13 and other less sensitive nuclei, and multiple pulse techniques were further revolutionizing the field. This was perhaps fortunate for me, as I was always uncomfortable in the 'rotating frame', and the very elegant multiple pulse experiments being introduced convinced me that it was time to move aside for younger and more agile minds. Still, it would have been great fun to start all over again.

Biographical Sketches

Raymond Craig Ferguson. *b* 1922. B.S., 1948, Chemistry, M.S., 1950, Analytical Chemistry, Iowa State University (Ames), Ph.D., 1953, Physical Chemistry, Harvard University, USA. Research at E. I. duPont de Nemours & Co., 1953–85. Introduced to NMR by William D. Phillips in 1954 and continued NMR work until 1974. Approximately 30 publications. Research specialties: molecular spectroscopy (gas-phase microwave, infrared, high-resolution NMR) of organic compounds and synthetic polymers, computer analysis of spectra, polymer characterization, polymer physics.

William Dale Phillips. *b* 1925. A.B., 1948, University of Kansas, Ph.D., 1951, Physical Chemistry, Massachusetts Institute of Technology. Research and research management, finally Associate Director of Basic Science, Central Research Department, E. I. duPont de Nemours (USA), 1951–74. Technical Manager, mycoprotein venture, The Lord Rank Research Centre, England, 1974–76. Assistant Director of Research & Development, Plastic Products & Resins Department, E. I. duPont de Nemours, 1976–78. Charles Allen Thomas Professor of Chemistry and

Chairman of Department, School of Medicine, Washington University, St. Louis, MO, 1977–84. Director, Center for Biotechnology, 1982–84. Senior Vice President, Science & Technology, Mallinckrodt, 1984–90. Associate Director, Office of Science & Technology Policy, 1990–91;

deceased, 1993. Research specialties: physical chemistry, molecular spectroscopy, particularly NMR, ESR and IR, biophysics, molecular and electronic structure of organic and inorganic compounds, polypeptides, nucleic acids and proteins.

Fiat Daniel: The International Society of Magnetic Resonance (ISMAR). Landmarks and Highlights

Daniel Fiat

University of Illinois at Chicago, Chicago, IL, USA

OBJECTIVES

The aims of the International Society of Magnetic Resonance are: to advance and disseminate knowledge of magnetic resonance and its applications in physics, chemistry, biology, and medicine among scientists and research institutions throughout the world; to foster interactions among scientists in different fields of magnetic resonance; to encourage interdisciplinary explorations; to organize schools, local and international symposia on magnetic resonance; and to publish articles and periodicals on this subject.

HISTORICAL BACKGROUND

In September 1965 an international symposium on nuclear magnetic resonance was held in Tokyo, Japan, chaired by Shizuo Fujiwara. This meeting was followed by a second international meeting held in Sao Paulo, Brazil, in July 1968 and organized by Leonard Reeves, E. Geisbrecht, and S. Mathias. A third meeting followed, held in Clayton, Victoria, Australia, in 1969. This meeting was organized by Clive K. Coogan.

At the closing session of the Clayton meeting, the participants recommended the formation of an International Society of Magnetic Resonance and elected myself as chairman for the purpose of founding the society.

In August 1971 the fourth international meeting on magnetic resonance, which I organized, was held in Rehovot and Jerusalem, Israel. This meeting marked the 25th anniversary of the discovery of nuclear magnetic resonance. Following the opening session the first award of the society—the ISMAR Prize—was presented to Erwin L. Hahn by Felix Bloch for the discovery of the spin echo phenomena and his many outstanding contributions to the field.

The International Society was formally founded following the 4th meeting and its constitution adopted by its founders: E. Raymond Andrew, Nottingham; Robert Blinc, Ljubljana; A. David Buckingham, Bristol; Clive K. Coogan, Clayton; Daniel Fiat, Rehovot; Shizuo Fujiwara, Tokyo; Karl H. Hausser, Heidelberg; Leonard W. Reeves, Waterloo; and John S. Waugh, Cambridge. These founders formed the Executive Committee. The Council consisted of the Executive Committee and the following members: George J. Béné, Geneva; Felix Bloch, Stanford; Jacques Danon, Rio De Janeiro; Sture Forsén,

Lund; Herbert Gutowsky, Urbana; Jacek Hennel, Krakow; Valdemar Kowalewski, Buenos Aires; D. Arthur Losche, Leipzig; A. K. Saha, Calcutta; Jacob Smidt, Delft; Ionel Solomon, Paris; and Ioan Ursu, Bucharest.

The Council recommended holding future ISMAR meetings triennially. Subsequently ISMAR meetings were held in 1974 in Bombay, 1977 in Banff, 1980 in Delft, 1983 in Chicago, 1986 in Rio de Janeiro, 1989 in Morzine, and 1992 in Vancouver. The 1995 meeting will be held in Sydney, Australia.

An attempt has been made to hold each meeting in a different continent to bring together scientists from the different fields of magnetic resonance: nuclear magnetic resonance, electron spin resonance, and nuclear quadrupole resonance; also to bring together scientists involved in the development of magnetic resonance techniques with those involved in the applications of the techniques in physics, chemistry, biology, and medicine.

ISMAR held International Schools and sponsored series of Specialized International Symposia in NMR, ESR, and NQR, oriented towards specific topics and applications that reflected the most recent and advanced developments. Schools were held jointly with the Groupment AMPERE in Yugoslavia. Schools in Italy were organized by the ISMAR sponsored scientific organization in Italy, GDRM.

The *Bulletin of Magnetic Resonance* is the quarterly review journal of ISMAR. Its first editor was J. Howard Bradbury, Canberra; its present editor is David Gorenstein, Purdue.

It is not possible to cover here all of the important developments in magnetic resonance and its applications; however, certain events at ISMAR meetings that demonstrate the great advances in magnetic resonance stand out in my mind. I would like to mention a few. I remember John Waugh in 1968, at the Sao Paulo meeting, eagerly awaiting a call from his students in regard to a novel method that would allow high-resolution studies of solids by a unique pulse sequence. The novel approach of John and his students led to developments of the utmost importance in nuclear magnetic resonance and its applications. The method was later combined with the high-resolution method developed earlier by Raymond Andrew, thus opening the way for detailed high-resolution studies of solids, leading to the development of many other novel techniques by the same investigators as well as inspiring important developments by others.

Among the many distinguished scientists at the small but intimate Clayton meeting in 1969 was J.H. Van Vleck, who participated and inspired most illuminating scientific discussions.

In 1971, at the Rehovot–Jerusalem meeting three large parallel sessions took place: one in physics, the second in chemical applications, and the third in biological and clinical applications of magnetic resonance. Lectures covered developments in nuclear magnetic resonance, electron spin resonance, and nuclear quadrupole resonance.

At the Bombay meeting, in 1974, the ISMAR Prize was awarded to Herbert Gutowsky for his outstanding achievements in the field of magnetic resonance and its applications to chemistry. Another major highlight of the meeting was the presentation by Paul Lauterbur of NMR ‘Zeugmatography’. As we well know, this innovative method provided the impetus for the development of magnetic

resonance imaging which has been found invaluable in the clinical field and has additional applications of utmost importance in the biological sciences and in studies of the physics and chemistry of solids.

At the Banff meeting, in 1977, the ISMAR Prize was awarded posthumously to E. K. Zavoiski, for his discovery in 1945, in Kazan, of electron paramagnetic resonance, and to Robert Blinc for his distinguished contributions in the applications of nuclear magnetic resonance to studies of collective motion near phase transitions, and for the development of a distinguished school in nuclear magnetic resonance in Yugoslavia.

The 1980 meeting in Delft was a large meeting, jointly held with the Groupment AMPERE, and brought together the European scientific community with the international community-at-large. It was a great success.

At the opening of the Delft meeting, ISMAR Prizes were awarded to Hans Dehmelt and to Gunther Laukien. The prize to Hans Dehmelt was awarded for his distinguished contributions to magnetic resonance and rf spectroscopy including his codiscovery with his doctoral advisor H. Kreuger, in 1949 in Göttingen Germany, of the nuclear quadrupole resonance phenomenon for the development, in Seattle, of techniques for studying atomic particles at rest in free space, resulting in the most precise determination of the electron g factor in free electron traps in 1976, and in 1979 for the most precise studies of magnetic properties of a single positron, the best test obtained so far of quantum electrodynamics. The ISMAR Prize for the industrial development of magnetic resonance instrumentation was presented to Gunther Laukien.

An active participant and a source of inspiration in the Rehovot–Jerusalem, Bombay, Banff, and Delft meetings, Felix Bloch contributed significantly to the scientific contents of the meetings. He was heavily involved in society matters in preparation for the Chicago meeting in August 1983. Unfortunately, the physics and magnetic resonance community suffered a great loss when Felix Bloch died on September 10 of that year.

The number of participants at the Chicago meeting was large, about 1000. At the meeting magnetic resonance physics, techniques, and applications in chemistry, biology, and medicine were presented and discussed. A very illuminating talk describing the development of magnetic resonance was

given by Norman Ramsey. The ISMAR Prize was awarded to B. Bleaney, Oxford, for developing the field of electron spin resonance.

Charles P. Slichter was awarded the ISMAR Prize at the Rio de Janeiro meeting (1986) in recognition of his pioneering work in nuclear magnetic resonance and its applications in solid state and surface physics. The Rio de Janeiro meeting was a great success, the participants included many of the pioneers in magnetic resonance as well as students and younger investigators.

John S. Waugh was awarded the ISMAR Prize at the Morzine meeting (1989) in recognition of his pioneering work in nuclear magnetic resonance and for teaching us all that spins can be made to do almost everything. Among the many important scientific contributions to the meeting were the lectures presented by Erwin L. Hahn, Richard R. Ernst, Charles Slichter, Ray Freeman, and Alexander Pines.

Paul Lauterbur and Peter Mansfield were awarded the ISMAR Prize at the Vancouver meeting (1992) in recognition of their important contributions to the fundamentals of nuclear magnetic resonance and its applications, especially their inventions of practical means of forming images which make it possible to determine and display the spatial variation of important physical, chemical, and biological properties of matter.

The absence of many of the pioneers of magnetic resonance and the participation of many younger investigators at this meeting marked the change of times. It was very moving to see Charles P. Slichter and Ray Freeman going from group to group discussing science with the new generation.

Forsén, Sture: ‘Saturation Transfer’ and ‘TSI’—Early Days and Nights of NMR in Sweden

Sture Forsén

University of Lund, Lund, Sweden

*An enterprising young woman from Thame
Took a trip in the rotating frame
She returned the next day
Most contented and gay
With no signs of repent or of shame.*

(Late night poetry from the Forsén and Hoffman labs; AD 1962)

The first two commercial NMR spectrometers (Varian, 40 MHz) arrived in Sweden in early and mid-1957. One was procured by Prof. Kai Siegbahn, a few years earlier appointed to the prestigious Chair in Physics at Uppsala University. The other was obtained by Dr. Erik Forslind, Associate Professor of Physical Chemistry at the Royal Institute of Technology (‘KTH’) in Stockholm. These instruments were actually not the first NMR spectrometers in Sweden. Dr. Gunnar Lindström at the Nobel Institute of Physics in Stockholm had, around 1950, built his own instrument. His magnet was of such good quality that he actually was one of the first, if not the first, to report ^1H NMR chemical shifts—between water and CH_2/CH_3 groups in mineral oil.¹ Lindström’s spectrometer was later modified by a Swedish medical doctor, Dr. Erik Odeblad, who used it for his pioneering biomedical NMR applications in the mid-1950s—the truly first *in vivo* experiments.² I am not quite sure for what purpose Kai Siegbahn had intended to use his Uppsala spectrometer. Possibly he had in mind originally to determine accurate values of nuclear magnetic moments—but the damned chemical shifts became an irritating obstacle and I think his interest faded gradually. Anyway, he had the good inspiration to send a young gifted graduate student, Ragnar Hoffman, to an introductory NMR course at Varian in Palo Alto in early 1957. At Palo Alto Ragnar learned about all the wonderful things that NMR could do in chemistry—knowledge that he brought back to his Physics Department colleagues who, however, now seemed all into atomic beams rather than messy liquids.

The instrument at the Royal Institute of Technology was originally intended for one particular research project: to elucidate the molecular properties of water in hydrogels, notably cement. The spectrometer thus had a ‘wideline’ attachment as well as the standard high-resolution parts. In early 1956 I had been enlisted as a teaching assistant at the Physical Chemistry Division and had come to know Dr. Forslind. After my M.Sc. in Chemical Engineering in mid-1956, I was snatched away into compulsory military service and was eventually transferred to the National Defense Research Laboratories in Stockholm. One day in early 1957

I received a phone call from Dr. Forslind who asked me to join him as his first ever graduate student and in charge of the NMR instruments. With some hesitation—my knowledge of NMR was rudimentary and I had seen pictures of spectrometer consoles that looked scarily like the gadget-crowded cockpits of commercial airliners—I accepted. During my free time I then started spending many hours in the library of the National Defense Research Laboratories reading early NMR articles and teaching myself quantum chemistry. In mid-1957 I was a civilian again, and joined Forslind’s group in time to see the heavy Varian electromagnet being lifted in through the windows of the Physical Chemistry labs on the second floor.

Meanwhile in Uppsala, Ragnar Hoffman had established contacts with the Organic Chemistry Department, especially with Assoc. Prof. Salo Gronowitz, an enthusiastic and successful expert on thiophene chemistry. He soon provided Ragnar with a number of mono- and disubstituted furans and thiophenes with interesting AB, ABC, and ABX spectra. The Hoffman–Gronowitz collaboration was very fruitful, a number of publications resulted and became the core of Ragnar’s Ph.D. thesis that he defended in late 1960—with Dr. Forslind and myself as opponents. Nearly the entire Swedish NMR community gathered in one room!

Assimilating the basis of NMR in those days was totally based on self-studies. The early monograph by E. R. Andrew (1958) was in many ways most valuable, but gave little insight on high-resolution NMR on liquids. So it was a struggle through the published literature—articles by Gutowsky, Pople, Schneider, Bernstein, McConnell, etc.—trying to learn as one went along. Ragnar, with his solid background in theoretical physics, had little problem with the spin Hamiltonian and soon became a master of analyzing ABC, ABX, AA’BB’, etc. spectra. I myself was for a long time occupied trying to make sense of the wideline spectra of Forslind’s hydrogels and performing crude quantum chemical calculations using analytical expressions (fitted using slow desk top calculators!) of numerical Hartree–Fock wavefunctions. Eventually I managed to swing my thesis towards experimental studies of hydrogen-bonding in liquids—a subject that fascinates me to this day. I also started collaborating with graduate students in the Organic Chemistry Division which under Prof. Holger Erdtman was largely directed toward studies of natural products from the plant kingdom. Erdtman was then known for his scepticism against the use of spectroscopic methods for structure elucidations. IR was just about acceptable. All that changed completely after a lecture at the Royal Institute of Technology by Sir Derek Barton in which he beautifully demonstrated the enormous benefits of ^1H NMR for structure elucidations of steroids, terpenes, etc.—studies mostly made in collaboration with Lloyd Jackman. Erdtman was completely converted to ^1H NMR from that very day, to my great benefit.

In 1959, after some dissension with my supervisor, I wrote up a licentiat thesis (old Swedish degree, more like a Ph.D. of today) on my hydrogen-bonding studies and left for a job at the Atomic Power Department of ASEA in Västerås—a town some 160 km west of Stockholm. I could, however, not abandon the NMR field—for a long time I was traveling back and forth between the Royal Institute and Västerås, running spectra on late evenings and weekends. Eventually I got a generous offer from Erdtman and Forslind to return to Stockholm with a lot of freedom to carry out my own NMR

research, as long as I kept the organic chemists happy with a spectral service. After an intense year of work, I defended my Ph.D. thesis (old system) in late 1962. The same autumn I met Ragnar Hoffman at an NMR meeting in Oxford. We soon discovered a common childish streak in our personalities and had a hilarious time trying to outsmart the ignorant and slightly xenophobic scouts at Balliol College—our place of lodging. We decided that we must start to collaborate—the question was merely on what. Double resonance was then one of the excitements of the day with the possibilities of determining the relative signs of spin coupling constants as pioneered by D.F. Evans, Ray Freeman, and David Whiffen. We decided to explore this and on our return to Sweden things moved swiftly. At the Royal Institute we had some hardware parts, e.g. an audiooscillator, that made it natural to do the experiments there. We worked enthusiastically and hard. Ragnar thought of experiments in terms of spin Hamiltonians and doubly rotating frames, while I tended to think in terms of energy level diagrams and of the chemical aspects of the molecules we looked at. We found that there were some variants of the double resonance technique that had not yet been explored—for example, selectively inverting the populations of the levels corresponding to a particular transition in a multispin system. This we introduced as ‘TSI’, i.e. transitory selective irradiation - an early NMR version of a ‘soft’ selective 180° pulse.³ We used the TSI method extensively for characterizing the coupling parameters in complex spin systems.

One day in early 1963, during a coffee break in Uppsala, I asked Ragnar semi-seriously what would happen if one were to irradiate an NMR signal from a proton that was not spin coupled to but in chemical exchange with another proton with a different chemical shift. Would anything happen at all? Ragnar hesitated, ‘I am not sure. Let us do an experiment!’ How to find a suitable chemical system? My previous experience with hydrogen-bonded organic molecules now came in handy. After some trial and error we had several candidates. One could for example mix a bulky aliphatic alcohol, like *t*-butanol, with a molecule with an intramolecular hydrogen bond, like 2-hydroxyacetophenone, and get two well-separated OH NMR signals. Also by gradually adding small amounts of an amine, one could increase the rate of chemical exchange between the two types of OH groups to the point of coalescence. So we could certainly test the new double resonance experiment at different exchange rates if need be.

Very late one night in May 1963 the experiment was tried out—a shot in the dark, literally! A modulated sideband was set on one OH signal while the intensity of the other was monitored by a rapidly repeated ‘Phantastron’ sweep—and lo and behold the observed signal gradually decreased in intensity to a new low value! Great excitement!! We eventually decided that the experiment was indeed reproducible and OK. Childish happiness and dancing on the lab floor ensued. One week later everything was wrapped up. The theory of the new ‘magnetization or saturation transfer’ method of determining moderately slow chemical exchange rates was developed mainly by Ragnar, and the first short communication was sent off.⁴ We soon carried out more experiments on different exchanging systems and wrote two detailed accounts of the

method.^{5,6} Thanks to John Baldeschwieler, we were also given an opportunity to present the new method as a late entry at the 1963 ENC in Pittsburgh.

The collaboration between Ragnar and myself was very intense for the following three years and in a way culminated in a rather extensive review on double and multiple resonance for the first issue of the new series *Progress in NMR Spectroscopy*.⁷ In 1966 I was appointed to the new Chair in Physical Chemistry at the University of Lund, some 600 km south of Stockholm and became rather busy with building up the new division and with teaching duties. Ragnar went for a sabbatical with John Waugh at M.I.T. and wrote a learned review article on the development of a very general matrix inversion formalism for calculating NMR lineshapes.⁸ In 1969 we decided to write a ‘down-to-earth’ and useful textbook on the analysis of high-resolution NMR spectra. During this work Ragnar started showing clear signs of strain and weariness. I understood that in order to obtain a tenured position as university lecturer in physics at Uppsala University he had to take courses in relativity theory, astronomy, and what not. Conscientious as he was, and despite the fact that he already must have been more than qualified for such a position, he vigorously committed himself to these studies. This, on top of his extremely heavy teaching loads and his strong desire to be an ever present family father, took a heavy toll on his health.

Ragnar passed away unexpectedly in early 1970, mourned by friends and colleagues near and far. I miss him tremendously. We had a great time exploring the rotating frame. I often wonder what great things he would be doing now.

Fraenkel, Gideon: Reminiscence of NMR

Gideon Fraenkel

Ohio State University, Columbus, OH, USA

University of Illinois, 1951. Herb Gutowsky taught us physical chemistry. Little did we know he had just discovered the chemical shift, a household word for future generations of chemists.

Harvard, 1955: NMR seemed a safe topic for the graduate student organic seminar, so obscure that a professor couldn't understand why the transition energies should depend on magnetic field. Not only had most organic chemists never heard of the Zeeman effect, they knew precious little about chemical physics in general. NMR changed all that. It became the conduit between organic chemistry and chemical physics.

Caltech days: After my rather structured experience at Harvard, I couldn't believe the no less intellectually demanding, informal atmosphere at Caltech. Everybody's door was open and everything seemed designed to facilitate the progress of research. I went there originally to work with Carl Nieman on enzyme kinetics. Instead, I literally got drawn to the NMR machine in Church Laboratory, then a Varian HR-40. Carl suggested we might learn something useful by looking at the NMR of amino acids. Unfortunately, the Jardetskys had just done that. Nieman was very supportive. He encouraged me to choose my own problems. This is how I got into the amide business.

It had always been assumed, but never proved, that amides protonate on oxygen, (**1**).

One day I had a mental image that in *N*-protonated DMF (**2**) there would be free rotation about the C_{CO}–N bond, whereas the *O*-protonated species (**1**) should show a barrier around this bond at least as large as that measured by Herb Gutowsky's group. So one would expect that (**1**) would exhibit nonequivalent methyls in the ¹H NMR spectrum at room temperature; needless to say this turned out to be the case. Amides were a favorite subject at Caltech, especially among Pauling's structure colleagues, and I became a popular person. The department gave me a Noyes Fellowship, so I continued to explore various physical organic problems, mainly via NMR.

One morning my lab mate Bob Carter (now at Astra Hassle) asked me if the cyclopentadienyl anion had fivefold symmetry. I assured him this was so but search the literature as we might, no crystallographic data were to be found. So we ran proton NMR on different salts, subtracted out the assumed ring current contribution (Pauling's formula), and then I looked at other symmetrical species (tropylium, benzene). Thus was born the linearity of sp² proton shift with charge. Around that time I was introduced to Andrew McLachlan who had recently justified from theory the linearity of hyperfine splitting with electron spin density. It seemed to him that our result could be handled in a similar fashion. We published a paper together. How did this all happen? It was the people and the atmosphere. Everybody went to coffee. I met Cafiero Franconi who worked with me further on amides. Aharon Lowenstein told me about kinetics from signal averaging. Because of Aharon, I eventually met and worked with Jerry Kaplan, the patron saint of density matrix theory applied to NMR signal averaging. People make a department. Jack Roberts really showed us by example that pretty complicated chemistry could be elucidated with NMR, Roberts more than anyone else.

First Gordon Conference on Magnetic Resonance: just boiling over with excitement, starting in the train from Boston; all the (now and later) famous names—Gutowsky, Bloembergen, Abragam, Hahn; people talking late into the night, new results just pouring out. I got to present the *O*-protonated amides. It turned out three other groups, Phillips (du Pont), Saunders (Yale), and Meiboom (Weizmann) had the same idea. But we were first. Next time around, the physicists wanted to scrap the conference. After all, everything had been worked out, correctly—the nuclear spin Hamiltonian, the Ramsey equation for chemical shifts, and the principal mechanisms for spin relaxation. Fortunately, calmer minds prevailed. Technical advances and the complexities of molecules have driven the field ever since. And Sputnik.

Research fellow and Noyes Fellow California Institute of Technology; introduced to NMR by John Roberts and Harden McConnell. Faculty in Chemistry, Ohio State University, 1960–present. Approx. 150 publications; research areas: reaction mechanisms, ion-pairs, dynamic NMR, carbanion chemistry.

Frahm, Jens: Toward Rapid NMR Imaging

Jens Frahm

Max-Planck-Institut für Biophysikalische Chemie, Göttingen, Germany

This article presents a personal view of our development of STEAM and FLASH NMR techniques in 1984 and 1985 at the Max-Planck-Institut für biophysikalische Chemie in Göttingen, Germany. To facilitate the understanding of the steps leading to rapid NMR imaging sequences, it will be helpful to start with some background information on NMR imaging as developed up to 1983–84 when we were first able to carry out experimental work on our own. Following some comments upon how the Göttingen project was set up, I will discuss our work on stimulated echo imaging sequences that led directly to the design of rapid low flip angle gradient echo imaging.

NMR IMAGING IN 1984

In 1984, the development of medical magnetic resonance imaging appeared to have reached a natural end. Following Lauterbur's original work¹ on the use of frequency-encoding magnetic field gradients for spatial discrimination of NMR signals in conjunction with a projection reconstruction algorithm for calculation of an NMR image, the onset of industrial development of the machinery by medical manufacturers around 1978–79 had led to considerable instrumental progress including the availability of 1-m bore superconducting magnets. Medical applications had focused on studies of the central nervous system and promised great sensitivity to detect abnormalities in a large number of disease states of the brain.

Even the image quality had become quite acceptable by combining several advances achieved between 1975 and 1981. Firstly, the preferred form of image reconstruction had been shifted from projection reconstruction to two-dimensional Fourier transformation (2D FT). This had been proposed by Kumar, Welte, and Ernst², who replaced the rotating frequency-encoding gradient of the Lauterbur experiment by a fixed frequency-encoding gradient and a variable phase-encoding gradient that probed the spatial distribution of spins along a second orthogonal dimension. Image calculation by 2D FT was in complete analogy to 2D NMR experiments for high-resolution structure elucidation such as 2D *J*-resolved or shift-correlated spectroscopy. Secondly, for practical implementations the spin warp modification of the phase-encoding gradient as described by Edelstein, Hutchison, Johnson, and Redpath³ provided technical simplicity and robustness with regard to image artifacts. Thirdly, plane definition by slice selection had been successfully accomplished by combining a frequency-selective shaped 90° rf pulse with a slice selection gradient. Following a controversy between Mansfield⁴ and Hoult,⁵ agreement was reached on the necessity to refocus the

dephasing effect of the slice selection gradient during the second half of the rf pulse by gradient reversal after the end of the rf pulse. And fourthly, an important step forward had been made by two research groups led by Young⁶ and Edelstein⁷ in adopting Hahn's spin echo rf pulse sequence⁸ for NMR imaging. The spin echo version overcame severe signal losses and instabilities that arose from magnetic field inhomogeneities due to technical limitations of the early wide-bore magnets and in vivo tissue susceptibility differences.

In view of the aforementioned accomplishments, a typical summary of the state-of-the-art in NMR imaging in 1984 might have been as follows. The spatial resolution of the images was considered acceptable for many medical applications and the accessible soft tissue contrast based on differences in T_1 and T_2 relaxation times turned out to be excellent. Foreseeable improvements were to be expected in technical areas such as the quality of hardware components (rf coils, preamplifiers, computers, etc.), the reduction of eddy currents associated with gradient switching, and the design of slice-selective 180° refocusing pulses that compensate for the nonlinearity of the Bloch equations borne out by long pulses and strong off-resonance effects in the presence of a gradient. Other issues concerned the handling and user-friendliness of the instruments and included multislice and oblique imaging procedures as well as respiratory and EKG-triggering and gating.

However, there was agreement that no major change was to be expected for the #1 problem in NMR imaging, i.e. the relatively long measuring times of the order of minutes. While typical repetition times were 500–2000 ms to ensure sufficient signal recovery, the reconstruction of a high-resolution image required at least 128–256 acquisitions with different phase-encoding gradients. Thus, the temporal resolution in NMR imaging appeared to be determined by physical limitations such as T_1 relaxation times and the principle of image formation. This problem was central to many applications and in a sense overshadowed the usefulness of NMR imaging as a whole when compared with competing modalities in diagnostic imaging. Obviously, long imaging times cause motion problems for cardiac and abdominal examinations as well as for less cooperative patients, and generally do not allow dynamic studies with a time resolution of seconds typical for many physiological processes. They also preclude the use of 3D NMR imaging studies since pertinent acquisition times would easily reach several hours. In this context Mansfield's development of echo planar imaging⁹ as a high-speed method was not considered to be an alternative for 'plain' imaging, due to a lack of image quality and limited spatial resolution as determined by the rapid decay of transverse magnetization from tissue water in most organ systems.

It was in this atmosphere that our small group of researchers at the Max-Planck-Institut für biophysikalische Chemie in Göttingen, Germany described a new concept for rapid scanning that marked a breakthrough in NMR imaging and led to a still growing number of new applications.

THE GÖTTINGEN PROJECT

My personal acquaintance with and first practice of NMR dates back to the mid-1970s when my scientific teacher Hans Strehlow offered me work on a diploma thesis where NMR T_1

relaxation differences were exploited to measure the kinetics of rapid chemical exchange reactions.¹⁰ The equipment I had to use was an old-fashioned 60 MHz Bruker electromagnet connected to a 'pulse spectrometer'. However, the lack of any Fourier transform analysis and the enthusiasm of Hans Strehlow gave me an excellent introduction into basic pulsed NMR experiments. Although our emphasis was solely on dynamic and kinetic aspects with applications in physical chemistry, the original experiments of Hahn,⁸ Gutowsky,¹¹ Carr and Purcell,¹² Woessner,¹³ Stejskal,¹⁴ Tanner,¹⁵ and many others involved in the development of 'zero-dimensional' NMR without chemical shift discrimination formed the ground for our later work in the *in vivo* field.

In the second half of the 1970s the Max-Planck-Institut für biophysikalische Chemie was an exciting place where many scientists trained as physicists or chemists started using their expertise to look into biological systems. Manfred Eigen developed the concept of the hypercycle as a model for biological evolution at the molecular level, Fritz Schäfer helped to turn the laser into a multipurpose instrument for biological research, and Erwin Neher and Bert Sakmann worked on electrophysiological recordings of single cells, to name only a few. In this environment a young scientist had to be attracted by the way discipline-crossing research was carried out. In fact, even a quick look into NMR immediately indicated its potential role in biology with noninvasive investigations of cells, excised organs, or even small laboratory animals.

At that time the 'ruling' NMR community showed only little interest in the future capabilities of NMR imaging and its need for serious scientific research to promote further developments and applications. Very little was known about those involved and their 'suspicious' contacts to industry or their 'dubious' collaborations with such disciplines as medicine or radiology. However, without prejudice I felt ready to make my own decisions in a critical postdoctoral phase of my scientific career and I was therefore very much influenced by the clear and positive messages of Lauterbur, Damadian, Mansfield, and Radda, who all lectured at the 1979 European Experimental NMR Conference in Autrans, France. Firstly, there was no doubt that access to 'spatial resolution' would be available to NMR researchers dealing with imaging or high-resolution spectroscopy, and secondly, the newly formed *in vivo* NMR community represented a fascinating melting pot for physicists, biologists, clinicians, and manufacturers who opened the way into a field where basic and applied research frequently fail to be distinguishable.

Although it took until early 1982 before we submitted a grant application to the Deutsche Forschungsgemeinschaft (DFG), it was still the first proposal for a research project that dealt with NMR imaging in Germany. The group of enthusiasts comprised Wolfgang Hänicke, a mathematician, who had worked with me on theoretical issues such as slice selection and time-variable frequency-encoding gradients in NMR imaging;^{16,17} Dietmar Merboldt, a physicist who was my first Ph.D. student and who had just finished a thesis on water proton NMR relaxation in ternary systems as a very simple model of heterogeneity in biological cells; Dieter Matthaei, a clinician from the University hospital of Göttingen with a background in internal medicine and Axel Haase, another physicist from the Max-Planck-Institut

who had just received a Ph.D. for his work on membrane-bound pH indicators which involved NMR experiments to characterize the exact location of the dye molecules. Provided DFG financial support was granted, Axel Haase had promised to join after his postdoctoral stay in Radda's lab in Oxford where he worked on surface coils and rotating frame imaging.

The DFG application focused on 'quantitative parametric' NMR imaging techniques that ought to be developed with use of an experimental 2.35-T 40-cm bore magnet. Unfortunately, the project was not only delayed by the DFG, who invited all German radiologists to contribute applications for NMR imaging, but was subsequently turned down by giving preference to two clinical applications based on 1.5-T whole body units: just another example of how bias in research funding and reviewing may affect scientific progress, particularly in countries that preclude proper outside refereeing by applications not being available in the English language. The reason why this article can be written is only due to the technical understanding and the personal courage of Friedrich Unz, who at that time was responsible for research grants from the German government, i.e. the Bundesminister für Forschung und Technologie (BMFT), and thus participated in the DFG decision as an observer. He decided to grant BMFT financial support for more or less the same proposal within a period of only three months, which then allowed us to start the project in July 1983.

In February 1984 a Bruker imaging and spectroscopy system was installed in Göttingen. At that time the manufacturing of high-field wide bore magnets was still a critical experiment and so there was no real surprise that the 2.35-T, 40-cm bore magnet had to be replaced only a couple of weeks later because of a significant field drift following a quench (as far as I remember it was finally up to 1 kHz h⁻¹). However, since then we have successfully worked with a second magnet, while the rest of the system has been upgraded several times. During the first weeks and months we worked through spin echo imaging and image reconstruction techniques, and rapidly learned that the practical reliability of some of the theoretical concepts was clearly limited by technological constraints such as rf power restrictions and magnetic field gradient eddy currents. However, we also identified a lack of investment in more sophisticated techniques as a potential source of some scientific and clinical disappointment in NMR imaging. Or in other words, the real problems were in physics and biology rather than in data handling and postprocessing. We therefore decided to focus on new methods that would enhance the specificity of the image information by providing better access to contrasts beyond spin density, T_1 , and T_2 .

Our first target was the loss of chemical shift information. Even for the simple case of water and fat components contributing to an object, no attempt was made to retrieve the chemical information for imaging. With the availability of shaped rf pulses and magnetic field gradients as required for imaging, however, a spectroscopic separation of water and fat proton NMR signals was easily accomplished by a suppression of the unwanted chemical shift component prior to data acquisition. The CHESS (chemical shift selective) technique simply excites the unwanted resonance with use of a frequency-selective rf pulse and then dephases ('spoils') the resulting transverse magnetization prior to the application of a subsequent imaging or spectroscopy experiment.¹⁸ The same principle is now commonly applied for water-suppressed

localized proton NMR spectroscopy or for solvent suppression in high-resolution NMR.

STEAM ...

Another area of interest was the NMR access to molecular dynamic information that might be adopted for imaging. Maps of microscopic mobility or 'diffusion' would not only be of scientific value in complex biological systems, but also serve diagnostic purposes in disease states. In fact, diffusion-weighted NMR imaging now seems to be the method of choice for the early detection of infarction zones in patients after a cerebral stroke. In the classical literature the stimulated echo sequence comprising three rf pulses had been demonstrated by Tanner¹⁵ to be particularly suitable for the investigation of systems with long T_1 and short T_2 relaxation times, as in proton NMR studies of biological tissue. In NMR imaging stimulated echoes had only occurred as artifacts originating from imperfect 180° rf pulses in multiecho sequences. In early 1984, Wolfgang Hänicke and Dietmar Merboldt therefore started to focus on NMR imaging experiments based on stimulated echoes. Computer simulations with variable numbers of slice-selective 90° rf pulses and different predephasing and rephasing strategies were rapidly followed by the implementation of basic STEAM (stimulated echo acquisition mode) imaging sequences on the Bruker scanner. The first positive results enforced a detailed theoretical and practical evaluation of the sequences' compatibility with imaging, i.e. slice selection, spatial encoding, and spoiling of unwanted spin echoes and FID signals. For example, we identified the complete dephasing of any transverse magnetization before the application of the second rf pulse as a prerequisite for ensuring maximum intensity of the stimulated echo. Interestingly, this was not properly claimed in Hahn's elegant paper on 'Spin Echoes',⁸ which in retrospect may be explained by the very short T_2^* relaxation times in the fairly inhomogeneous magnets available in 1950.

The relatively easy and successful development of a completely new imaging concept stimulated our optimism considerably about further substantial progress in NMR imaging, which in 1984 was partly in contrast to published suggestions by industrial researchers and clinicians. In our group almost every day somebody came up with a new idea on how to improve the versatility of the STEAM imaging sequence.¹⁹ Dozens of modifications and variants were developed between the summer and fall of 1984 and filed as a German patent application on December 14, 1984. Although diffusion imaging²⁰ was the original impetus, applications extended to new forms of bolus-tracking flow imaging,²¹ CHESS imaging,²² and even localized spectroscopy²³ which later became a major tool in our efforts to study human brain metabolism. In addition, we recognized the potential of measuring T_1 relaxation processes by varying the middle interval T_m between the second and third rf pulse rather than by changing the repetition time. This form of T_1 -weighted imaging was somewhat similar to measuring T_2 relaxation by an echo train. In fact, multiple readout points with different T_m intervals could be obtained within a single STEAM sequence by subdividing the available longitudinal magnetization with the use of several low flip angle read pulses. This series of

pulses replaced the single 90° rf pulse in the third position of the basic stimulated echo sequence. By iteration it was possible to calculate the flip angles of any given number of pulses that created equal amounts of transverse magnetization, each of which was then differently T_1 -weighted according to the actual T_m value.

We realized as an important aspect of the STEAM T_1 imaging sequence²⁴ that it distinguishes between two types of longitudinal magnetization created during the course of the sequence. This refers to the pre-encoded longitudinal magnetization originating from the first two rf pulses that refocusses as a stimulated echo and to the longitudinal magnetization recovered from T_1 relaxation during the sequence. The latter magnetization contributes to the FID signal excited by any third read pulse. Thus, even large numbers of low flip angle read pulses followed by short stimulated echo acquisition intervals would not lead to a complex overlap of intermingling coherences. These considerations gave birth to the high-speed STEAM imaging idea. All we needed to do was to phase-encode differently a sequential series of frequency-encoded stimulated echoes that were created by two leading 90° rf pulses and a series of slice-selective low flip angle read pulses.²⁵

... AND FLASH

Our first high-speed STEAM images had imaging times of 200–1200 ms and created tremendous excitement. However, despite the fact that more recent implementations have demonstrated considerable potential for rf refocused high-speed cardiac imaging²⁶ and motion-insensitive diffusion-weighted imaging,²⁷ the sequence exhibits limited signal-to-noise because of its partitioning of (half of) the initially excited equilibrium magnetization into small portions for data acquisition. Instead of wasting the recovered longitudinal magnetization, it would be much more advantageous to exploit its feedback by T_1 relaxation with the use of multiple *excitation* pulses. Thus, as soon as the potential of multiple low flip angle *read* pulses in STEAM had been recognized, we thought of applying the concept directly to the equilibrium magnetization. This would eliminate the leading two 90° rf pulses in the high-speed STEAM sequence and then require phase- and frequency-encoding the spatial information into a gradient-recalled echo rather than into an rf refocused stimulated echo. Although the schematic rf pulse and gradient switching scheme was rapidly drawn on a sheet of paper, its actual implementation was somewhat slowed down due to discussions about potential coherence transfer problems that might occur during the rapid imaging process. Nevertheless, we finally decided to run an experimental trial since the amount of any residual transverse magnetizations would be very small due to both the small tip angles used and the short T_2^* relaxation times encountered in living tissues.

It was on a Friday morning around 10 a.m. that all members of the group gathered together to implement a low flip angle gradient echo sequence with a short repetition time. Of course, with regard to its simplicity, it could have been done within 30 min. However, the implementation was carried out piece by piece with some kind of aesthetic care and suspenseful slowness. It was quite obvious that everybody knew that we were close to a major breakthrough in NMR imaging

and everybody wanted to experience fully the excitement at the end. At noon we had our first results, i.e. FLASH (fast low angle shot) images of a water-filled beaker and—a few minutes later—of a human hand that demonstrated a tremendous gain in signal-to-noise ratio when compared with high-speed STEAM images. The measuring times were 1.92 s using a 128×128 data matrix and a repetition time of 15 ms. Over the weekend multiple versions were developed including dynamic scanning by sequential acquisitions and rapid three-dimensional imaging. And we agreed upon the acronym 'FLASH'.^{28–31}

In contrast to high-speed STEAM and echo planar imaging, the measuring time of a FLASH sequence is not limited by physical properties such as the duration of a relaxation time. The new concept offered an unrestricted and user-dependent choice of spatial and temporal resolution so that speed may be traded-off for resolution and image quality (signal-to-noise). Although *subsecond* FLASH imaging has found some useful applications,^{32–34} the main potential seems to lie in the fast scan domain where cross-sectional images of conventional quality may be acquired within seconds, while three-dimensional data sets need measuring times of minutes.

On February 12, 1985 we filed a German patent application. It was also decided to submit Abstracts to the 1985 Annual Meetings of the Society of Magnetic Resonance in Medicine (SMRM) in London and the Radiological Society of North America in Chicago. To maximize the expected 'big bang' in NMR imaging we thought it worthwhile not to publish journal articles prior to our oral presentation of 'NMR movies' at the SMRM in August. Unfortunately, the planned surprise failed completely since we felt safe in disclosing our information on FLASH scanning shortly before the SMRM meeting to manufacturers involved in the industrial development of medical NMR imaging. We simply forgot about the ease of implementation of the sequence and the speed of modern communications. For example, Derek Shaw of General Electric immediately recognized the potential of the FLASH concept during his visit to Göttingen a week before the SMRM. He transferred the information to Milwaukee where Gary Glover implemented the sequence on a 1.5-T scanner and obtained good quality FLASH images of the human abdomen. Without knowing about these experiments we were therefore quite shocked upon arrival at the Barbican Centre in London, where last minute posters announced '2-s images' as General Electric's most recent achievement just imported from Milwaukee. In fact, we had a hard week in defending our invention against the publicity of a big manufacturer, in particular since the SMRM program committee had scheduled our presentation on the last day of the 5 day meeting. Nevertheless, the first NMR movie showing the dynamic flow pattern in a water beaker after stirring and the inflow of a paramagnetic contrast agent into the kidneys of an anaesthetized rabbit was a great success in demonstrating the new dimension the FLASH concept had added to NMR imaging. And without access to a whole body machine in 1985, we were extremely pleased by the quality of FLASH images obtained on commercially available medical NMR imaging systems.

Of course, many extensions and improvements have followed the early work. Among these are at least two areas that are based on FLASH sequence properties that were originally considered as disadvantages in giving rise to unwanted image

artifacts. The first is NMR angiography, which exploits the sensitivity of FLASH images to a continuous inflow of unsaturated spins from water protons within blood for a noninvasive delineation of the vasculature, while the second more recent application is based on the sensitivity of the gradient echo to magnetic field inhomogeneities or tissue susceptibilities. The latter effect may be used for functional NMR imaging of brain activation, since regional increases of cerebral blood flow associated with task performance result in a decrease of the concentration of paramagnetic deoxyhemoglobin in red blood cells.

In summary, the advent of rapid scanning NMR imaging has not only improved our access to high-resolution anatomy but opened the way to physiological insights into the human body.

Biographical Sketch

Jens Frahm, b 1951. Dipl.Phys., 1974, Ph.D., 1977, Physical Chemistry, University of Göttingen, Germany. Introduced to NMR by Hans Strehlow, research assistant at the Max-Planck-Institut für biophysikalische Chemie in Göttingen, 1977-1992, Head of Biomedical NMR Group, 1982-1992, Head of Biomedizinische NMR Forschungs GmbH, 1993-present. Approx. 165 publications. Research specialty: NMR studies of living systems; anatomic, metabolic, and functional aspects of intact organ systems; NMR imaging, localized NMR spectroscopy. Current interests: biochemical and physiological studies of the living human brain, functional organization, cerebral metabolism, brain disorders.

Fraissard, J.: A Look at Solid Catalysts by NMR

J. Fraissard

Université Pierre et Marie Curie, Paris, France

After beginning my higher education in the rather too sunny climate of Algiers, I came to the University of Paris and, perhaps because of the less disturbing climate, passed out of the Sorbonne in 1957 as top student of that year. Thanks to this result I went to the Laboratory of General Chemistry of the Faculty of Paris as a postgraduate to do thesis work, under Boris Imelik, on the study of the structure and properties of silica gels. Boris Imelik was at the time one of the most outstanding French experts on catalysis and surface chemistry. Although he ended his career as Director of the highly prestigious Institut de Recherche sur la Catalyse (IRC) in Villeurbanne, his international reputation was not what it might have been, probably because of his reluctance to travel and to speak in public.

The techniques used at the time for the study of solid catalysts were X-ray diffraction for the structure, IR spectroscopy and specific chemical reactions for the nature of surface hydroxyls. I naturally continued with this type of research. I think I was the first to show that IR spectroscopy could also be very useful in studying microstructures when the particles are too small to give X-ray diffraction diagrams. Above all, although solid state NMR was in its infancy, I realized in 1958 the interest of this technique for obtaining unique information about the nature and the distribution of the constitutive water of silica gels, as well as about the mobility of the protons at the surface of these solids. These characteristics are in fact all-important for understanding the behavior of solid catalysts with Brønsted acidity. I then went to work with I. Solomon in the already famous laboratory of Professor A. Abragam. I hope you will forgive the young scientist because I did not realize until much later how much science and intelligence it housed. There was, above all, Anatole Abragam, whose 80th birthday has just been celebrated in Paris by the entire international NMR community. But also, in no particular order, José Ezratty, Jean Combrisson, André Landesman, Jacques Winter, Charles Ryter (later to become an astrophysicist), Maurice Gueron (now a biologist at the Ecole Polytechnique), Maurice Goldman (who later took over as head of the laboratory) whose knowledge, patience, and modesty are always very impressive, and, of course, Ionel Solomon, nicknamed by Abragam 'the long-legged spinner', now Professor at the Ecole Polytechnique, who made me understand the power of NMR and to whom I owe my taste for spectroscopy. I was also able to rub shoulders with many eminent visitors, such as Richard Bersohn, Ray Freeman, Ralph Livingstone, Robert Pound, Warren Proctor, Alfred Redfield, et al.

The signal of the protons of silica gels was at that time very difficult to detect because of their low concentration, their relatively long relaxation times, the width of the lines, and the low sensitivity of NMR at frequencies below 16 MHz. However, by using strong radiofrequency fields in the dispersion mode, I was able to obtain signals with an adequate signal-to-noise ratio and to distinguish quite clearly for the

first time the characteristics of the OH groups of xerogels and aerogels, both from the point of view of the distribution and of the mobility of the superficial protons.¹ These results earned me the French Chemical Society prize in 1962.

Then, starting from Redfield's and Solomon's theories, I carried out a theoretical study of the variation of the NMR dispersion signal for a set of nuclear spins. This was achieved using both the spin relaxation times T_1 and the modulation period T_m of the sinusoidal magnetic field of low amplitude which was superposed on the field B_0 when the signal was amplified using the 'lock in' detection of the old spectrometers. The curves vary with the relative values of T_1 and T_m . Using the general signal equation, I was able to show how these curves could be used to determine the parameters of the nuclear spin considered.²

These results were then applied to many solid catalysts provided it was possible to obtain a decent NMR signal. Comparison of the theoretical and experimental signals allowed me to observe that the distribution of the surface OH groups depends on the nature of the solid and on the preparation of the sample. In certain cases the hydroxyls are distributed in small zones with a maximum local density; dehydration is moreover very inhomogeneous, the elimination of OH proceeding zone by zone. In other cases the hydroxyls are distributed statistically over the surface, regardless of the treatment temperature. NMR also makes it possible to determine the exact role of the different faces of the microcrystallites: some are absent or dehydrated during the formation of the solid, others have contiguous OH zones up to high temperatures.^{1,3-5}

I have for more than 20 years been the director of a large laboratory whose activity is mainly concerned with the study of the surface properties of solids, of gas-solid interactions, and of the mechanisms of heterogeneous catalysis. I shall only mention here a few of these original research projects based on the use of NMR.

I was also the first, as early as 1959-60, to show that high-resolution NMR could provide interesting information about the structure of activated complexes. The spectrum of an adsorbed molecule presents a certain number of perturbations as compared with that of the isolated molecule: certain lines are broadened, others are shifted. These variations in the chemical shifts depend on the adsorbant and on the adsorbate and its various functional groups. They relate to the change in the electronic configuration of the molecule upon adsorption and therefore allow one to determine the electronic configuration of the complex formed. For example, the spectrum of formic acid adsorbed on an insulator such as silica gel or alumina shows only one line due to the CH group. The OH group is the seat of the adsorption phenomenon and the characteristic line becomes too broad to be detected by conventional high-resolution NMR.⁶ In the same way, NMR enabled me to reveal four successive structures of butenes chemisorbed on silica-aluminas and then to determine the mechanism of the isomerization of butenes on these solids.⁷

It should be remembered that the chemical shifts of adsorbed phases can only be measured with respect to internal references. I showed, by ^1H NMR study of the physical adsorption of certain gases, how the necessary corrections can be made, in particular by determining the volume susceptibility of a powder with an accuracy, expressed in chemical shift, of about 0.3 ppm. This technique, which is now used by

everyone, makes it possible to classify the chemical shifts of heterogeneous systems with respect to the classical references of homogeneous systems.⁸

Modern high-resolution techniques for solids have confirmed my results, but have also led to a dramatic increase in the application of NMR to the study of heterogeneous gas–solid systems. However, the new techniques cannot always be used. For example, paramagnetic systems are generally studied by EPR. I have, however, shown that in many cases the amount of information provided by NMR is much greater: value and sign of the electron–nucleus coupling, distribution of the electron spin densities on the various nuclei of the chemisorbed complex, etc. For example, the large but opposite chemical shifts of the C and H of the CH group of HCOOH chemisorbed on slightly reduced TiO₂ demonstrate that there is a transfer of positive electron spin density (and, in this case, of electronic charge) from the solid to the antibonding π orbital of the COOH group. This transfer explains the catalytic power of the surface electron-donating Ti³⁺ in the dehydration of this acid.⁹ It should be remarked that the signals of these chemisorbed complexes are very broad. They cannot be narrowed by modern high-resolution NMR techniques. Only the technique of rapid exchange of physisorbed and chemisorbed molecules, developed in my laboratory, allows the determination of the chemical shifts characteristic of the chemisorbed complex.

I have also involved myself in the study of the Brønsted acidity of solids. Techniques used before 1970 (IR spectroscopy, colored indicators, etc.) were incapable of giving a precise comparison of the acid strength of solids. I was the first to suggest (later shown to be incorrect) that the acidity of an OH group depends on its polarization and may therefore be characterized by the chemical shift of the hydrogen. At that time, in the absence of any high-resolution NMR technique (MAS, CRAMPS), the chemical shift of the protons of solids could not be measured directly because of the large dipolar broadening of the signals. I showed that in the case of OH groups located on the surface of catalysts it was possible to narrow the proton signals by rapid exchange with adsorbed molecules and to calculate from these signals the shift, $\delta_{\text{OH}}^{\text{H}}$, of the OH group, provided the molecules adsorbed had two detectable spins (e.g., ¹⁵NH, ³¹PH₃, etc.); from the value of $\delta_{\text{OH}}^{\text{H}}$, it was then possible to deduce the electronic environment of the H atoms.¹⁰ The values of these shifts were checked much later by ¹H MAS NMR (Pfeifer's team). Unfortunately, measurement of $\delta_{\text{OH}}^{\text{H}}$ values in the absence of any adsorbed phase cannot possibly characterize the intrinsic acidity of the OH group. The perturbations (such as hydrogen bonds) due to their natural environment are far from negligible. Furthermore, the acid strength of O–H groups depends not only on the polarization of this bond but also on its polarizability. Hence the need to study it in the presence of an adsorbate.

This is why I have recently proposed a new procedure for at last defining a true acidity scale for solids. I have replaced the interactions of the OH groups with their ill-defined environment by a specific OH–B (basic molecule) interaction, where the adsorbed molecule B is H₂O, in order to bring the problem closer to that of aqueous solutions. To eliminate the fast exchange of protons between the different species, the spectra are recorded at 4 K and the dipole interactions are

capable of defining the equilibria

The software for the simulation of the spectra corresponding to the dipolar interactions of these species and of their mixture has been written. By using a powerful computer it is then possible to search for the several parameters (sometimes 10) required to simulate the spectra and hence to demonstrate quantitatively the various surface species and, in particular, to determine the dissociation constant of OH.¹¹

I have also proposed many other techniques for studying solid catalysts, in particular those which use probes which can be detected by NMR. Let me give two examples.

(a) The ¹H NMR study of hydrogen adsorbed on metals: the physical and electronic properties of metal particles, in particular their magnetism, depend on their size, at least when they are sufficiently small. NMR could therefore prove to be an interesting technique for studying these properties. As Slichter showed for platinum, the detection of the supported metal can provide precise data about its dispersion. However, this leads to considerable theoretical and experimental problems which prevent it being used as a routine technique. For this reason I proposed, well before Slichter's work,¹⁰ studying metal surfaces by NMR, but with the help of a gas such as hydrogen which can be chemisorbed by all metals and therefore used as a universal probe. Hydrogen has the advantage of high sensitivity of detection and of being one of the gases most used in catalysis. The main results obtained are as follows.

1. The chemical shift of hydrogen adsorbed on a metal is very high (Knight shift), and is positive or negative depending on the metal.
2. At 25°C, for a given metal, the value of δ extrapolated to zero concentration depends on the particle size and the temperature of chemisorption. It is often even possible to detect several signals corresponding to sets of particles of sufficiently distinct size. This result is particularly interesting when the particles are too small to be detected by electron microscopy.¹²
3. In the case of palladium, NMR is capable of distinguishing the α - and β -hydrides in equilibrium with the adsorbed phase.¹³
4. During the preparation of bimetallic catalysts, Pt–Au for example, this technique allows the reduction of the first metal to be followed, then the second, then (or at the same time) the formation of the small alloy particles. This technique has since been used by many researchers on various metals and alloys.

(b) The study of microporous solids by ¹²⁹Xe NMR of adsorbed xenon: The fundamental idea of this new research was to find a chemically inert molecule which was particularly sensitive to physical interactions with its environment and which could be used as a probe to determine the special properties of zeolites and, more generally, of microporous solids. This probe should, moreover, be NMR detectable since this technique is particularly well adapted to the study of the electronic perturbations of molecules undergoing rapid movement. I found that xenon is an ideal probe in this respect. Thus it is an inert gas, monoatomic, with a very

large, spherically symmetrical electron cloud. Any distortion of the latter is felt directly at the level of the nucleus and is consequently expressed as a variation of the chemical shift. From the NMR point of view the ^{129}Xe isotope is particularly suitable: it has a spin of $\frac{1}{2}$, its natural abundance is 26%, and its detection sensitivity is good (10^{-2} compared to that of the proton).

I have shown that the chemical shift of xenon situated in any system is always the sum of terms corresponding to the various perturbations to which it is subjected.¹⁴

$$\delta = \delta_{\text{ref}} + \delta_{\text{S}} + \delta_{\text{Xe}} + \delta_{\text{SAS}} + \delta_{\text{E}} + \delta_{\text{M}} \quad (2)$$

δ_{ref} is the reference. For a solid with no electric charge, δ_{S} (δ extrapolated to zero concentration) depends on the mean free path, l , of the xenon imposed by the structure of the zeolite. The quantity l depends on the dimensions of the cages and the channels and on the ease of diffusion of the xenon in the crystallites. The term δ_{Xe} expresses the influence of the Xe–Xe interactions, δ_{SAS} represents the influence of strong adsorption sites (which are generally cations, more or less charged, and sometimes paramagnetic), and δ_{E} and δ_{M} correspond to the effects of the corresponding electric and magnetic fields, respectively.

By means of this technique it is possible to determine the dimensions and form of the internal free volumes of zeolites without knowing their structures; to reveal structure defects produced, for example, by dealumination, and to determine their characteristics; to calculate the short-range crystallinity, as opposed to that determined by X-rays; to follow the mechanism of the synthesis and crystallization of zeolites during their preparation; to locate cations in the zeolite structure and to follow their migration or the change in their environment depending on various factors; to locate any ‘encumbering’ species, for example, adsorbed molecules, extraframework species, coke formed during catalytic cracking reactions, etc.; to determine the dispersion of metals (particularly when the particles are too small to be seen by electron microscopy) and the distribution of the molecules adsorbed on the particles (as opposed to the mean coverage); and to compare the diffusion of species as a function of the size of the zeolite ‘windows’.

This technique can also be applied to any microporous system^{15,16} (amorphous solid, polymer, clay, etc.). This list of applications is certainly not exhaustive. The power of this technique explains why it is currently used by most of the biggest companies which synthesize or employ zeolites and microporous solids.

Centre National de la Recherche Scientifique 1960–63; University of Paris, 1963–present. Approx. 180 publications; five books including ‘Thermodynamics and Kinetics’ and, with R. Mahé, ‘Chemical Equilibria in Aqueous Solutions’. Co-editor of four NATO ASI Series on Magnetic Resonance Applications: ‘Colloid and Interface Science, Fossil Energy’ and ‘Acidity of Solids’. Research interests: applications of solid state NMR to problems of gas–solid interactions and catalysis.

Freeman, Ray: Double Resonance Methods in High-Resolution NMR

Ray Freeman

Cambridge University, Cambridge, UK

When magnetic resonance methods were first introduced, they differed from other contemporary spectroscopic techniques in two important respects. The radiation was *coherent*, and in this sense NMR and ESR were leading the way, demonstrating what laser spectroscopy would accomplish many years later. They also offered the possibility of double resonance experiments long before they were dreamed of in optical or infrared spectroscopy. This idea that one could *manipulate* NMR spectra seemed new and attractive, a tiny hint of the forthcoming explosion of ‘spin gymnastics’ experiments that have made modern NMR so exciting. There were already some pioneering double resonance experiments by F. Bloch,¹ V. Royden,² A. L. Bloom and J. N. Shoolery,³ and W. A. Anderson.⁴ In 1959, I set out to try my hand at proton decoupling⁵ on a Varian 60 MHz spectrometer using Robert Pound’s idea that modulation sidebands could be used for the excitation of NMR signals.^{6,7}

Bloom and Shoolery’s paper on ^{19}F – ^{31}P double resonance³ seemed to hold the key to the theory, but when we tried to extend these calculations to predict the observed frequency dependence in proton–proton decoupling experiments, things did not seem to fit. The head of the ESR group of our laboratory, David Whiffen, was able to resolve the dilemma overnight. My mistake had been to assume that sweeping the field was equivalent to sweeping the radiofrequency. However, in double resonance experiments there is a significant difference, since a magnetic field sweep is equivalent to sweeping the frequencies of both B_1 (the observation field) and B_2 (the perturbing field), keeping a fixed separation between them. A true frequency sweep double resonance experiment would keep the frequency of B_2 fixed while scanning the frequency of B_1 .

To check these ideas on the spectrometer was not straightforward since at that time there were no facilities for frequency sweep high-resolution experiments. However, Hans Primas⁸ in Switzerland had just suggested a revolutionary idea for field/frequency control using the *internal* reference compound, tetramethylsilane, and this seemed to offer the way to test the new double resonance predictions that David Whiffen had worked out. So we introduced yet another modulation sideband⁹ to excite the dispersion-mode response of tetramethylsilane and derive an error signal to feed to the galvanometer of the Varian ‘superstabilizer’. If the field drifted one way this error signal would be positive, if the other way it would be negative. The TMS signal was monitored as a Lissajous figure on an oscilloscope. You can imagine our joy when, on closing the switch, the Lissajous figure stayed rock solid, indicating that the field/frequency ratio was stable within a few parts in 10^{10} , something we had never imagined possible. We were able to demonstrate that field sweep and frequency sweep

proton–proton double resonance experiments did indeed give quite different results, in accord with the calculations. Later, of course, ‘internal lock’ became the universally accepted method of stabilization and is still used today, with deuterium, rather than protons, as the reference signal.

SELECTIVE DECOUPLING

So far we had a cure looking for a suitable disease. What could one actually do with double resonance? A colleague from my graduate student days at Oxford provided one interesting application. Dennis Evans¹⁰ had been studying the proton NMR spectrum of the thallium diethyl cation, where the Tl–H couplings are so large that they are comparable with the chemical shifts, giving two methyl resonances and two methylene resonances, all well separated from each other. Dennis realized that it was not at all certain which methyl resonance went with which methylene, but that he could determine this by a selective decoupling experiment in which only one of the methyl resonances was irradiated. We can think of this as asking a ‘Maxwell demon’ to separate molecules with ^{205}Tl in an α spin state from those with ^{205}Tl in a β spin state so that the proton spectra of the two ethyl groups can be displayed separately. The ‘effective proton chemical shifts’ involve the magnitudes and *signs* of the Tl–H coupling constants, so here was a new method for determining relative signs of J couplings.

When Dennis Evans described this elegant experiment to David Whiffen, we realized that similar measurements of relative signs of coupling constants could be performed for *any* three-spin system, for example three protons, if only the irradiation could be made sufficiently selective. One proton (M) of an AMX spin system remains passive in the experiment, simply generating weak local fields at the A and X protons. This creates two AX subspectra, and we perform a decoupling experiment in one subspectrum with minimal perturbation of the other, thus distinguishing the ‘ α molecules’ from the ‘ β molecules’, just as if our Maxwell demon had been at work. Figure 1 shows the proton spectrum of 2,3-dibromopropanoic acid with A and X transitions assigned to α and β spin states of the passive spin M *assuming* opposite signs of J_{AM} and J_{MX} . In the lower trace a selective decoupling experiment confirms this assumption. Two decades later it became possible to obtain similar results from two-dimensional correlation spectra¹¹ where the presence of the passive spin M in an AMX

Figure 1 Selective decoupling of protons in 2,3-dibromopropanoic acid. The spin states of the passive spin M have been assigned *on the assumption* that J_{AM} and J_{MX} have opposite signs; this is borne out by the double resonance experiment (lower trace)

system determines the form of the AX cross peaks, giving the relative signs by inspection.

After some initial reluctance, chemists began to use selective decoupling to identify proton resonances that were related by a spin–spin coupling. Today we would call this ‘chemical shift correlation’. The additional equipment required for homonuclear double resonance was minimal—a stable audiofrequency oscillator usually sufficed. Several tricky assignment problems were resolved by these simple homonuclear decoupling experiments. With the advent of two-dimensional NMR, selective decoupling has been superseded by correlation (COSY or TOCSY) spectroscopy.^{12,13} In the abstract of his notes for a summer school, Jeener¹² comments that two-dimensional spectroscopy provides the same information as double resonance, but does it more efficiently. Indeed, most present-day two-dimensional experiments are essentially more sophisticated manifestations of earlier double resonance techniques.

SPIN TICKLING

I had always admired Wes Anderson’s work at Varian Associates, so given the opportunity to take sabbatical leave I joined his group in late 1961. At that time there were several excellent physicists working in the Varian Instrument Division, and their enthusiasm was such that they held evening seminars in various scientists’ homes, with slide projector, coffee, and cakes provided. I had only been in California a few days when, as the newcomer, I was ‘railroaded’ into giving the next evening seminar. I described David Whiffen’s calculations and showed the frequency sweep double resonance spectra we had obtained in England. During question time, one of the Varian scientists, Harry Weaver, pointed out that the spectra obtained at low irradiation levels appeared to show evidence of ‘spin tickling’ effects. This was an expression that several people had used without really *defining* exactly what it meant, but the essence was to set the B_2 level so low that only a single NMR transition was affected. This contrasted with spin decoupling, where an entire spin multiplet was irradiated. Looked at in this light, the frequency sweep double resonance spectra on my slides did seem to show tickling effects, and Wes Anderson and I decided to explore this idea further, exploiting the enhanced stability that could be obtained with the new internal field/frequency lock scheme.

It turned out to be an interesting phenomenon.¹⁴ Tickling a given NMR transition splits several other transitions into doublets. These are the ‘connected’ transitions, those that share an energy level with the irradiated line. The observed splitting is equal to $\gamma B_2/2\pi$ (Hz), and this provides a convenient calibration of the irradiation field intensity B_2 . If the irradiation field is not quite set to exact resonance, the observed doublet becomes asymmetric, one component getting weaker (eventually becoming a forbidden transition) while the other gets stronger (eventually reverting to the normal, allowed transition). Clearly we were dealing with an energy level noncrossing rule similar to that governing Fermi resonance in infrared spectroscopy.

At first we were puzzled to find that some doublets appeared to be better resolved than others in the same spin tickling spectrum. It turned out that the effect was real and that the explanation was rather subtle. Two transitions can be

Scheme 1

connected in two different ways; they can be *progressive* or *regressive* (Scheme 1).

Note that the progressive configuration is associated with a double quantum transition $\Delta m = 2$ whereas the regressive case involves the zero quantum transition $\Delta m = 0$. The tickling doublets arise from a quantum-mechanical mixing of allowed and forbidden transitions, such that both become equally allowed at exact resonance for the irradiation field, just as in Fermi resonance. The doublets with some double quantum character (the progressive case) are poorly resolved since the broadening by magnet field inhomogeneity is aggravated under these conditions, whereas the doublets with some zero quantum character (the regressive case) have the field inhomogeneity effect partly compensated and are better resolved. Thus the observation of a spin tickling doublet establishes that two transitions are connected and also indicates whether the configuration is progressive or regressive. Figure 2 shows the first spin tickling results obtained with the two-spin system 2-bromo-5-chlorothiophene, demonstrating a well-resolved and a poorly-resolved doublet.

For regressively connected transitions, when the B_2 field intensity is turned down even further, it is possible to ‘burn a hole’ by double resonance.¹⁵ The frequency selectivity is so high that only a localized region of the sample is saturated, while other parts (in slightly different applied magnetic fields) are too far from resonance to be significantly affected. If the frequency of B_2 is moved to another point on the profile of a chosen transition, the corresponding ‘hole’ in a regressively connected transition moves in concert. This turns out to be one of the most accurate methods for measuring frequency separations in high-resolution NMR; the observed line profiles are sensitive to as little as 0.001 Hz changes in the irradiation frequency.

In the early 1960s, when there were many cases of strongly coupled proton spectra, the first step of computer analysis was the assignment of observed transitions to the appropriate energy level diagram. Spin tickling was therefore a very useful assignment aid. It also picked out the subspectra that indicated the relative signs of coupling constants. With the new high-stability field/frequency lock, it was possible to reverse the spin tickling experiment, holding the observing field B_1 at the peak of a chosen transition and sweeping the perturbing field B_2 through the spectrum to search for connected transitions, where there would be a dip in the monitored signal. This ‘INDOR’ technique¹⁶ is useful for locating weak or hidden transitions.

Quite by accident, Jim Ferretti at Berkeley discovered an interesting variant of the INDOR experiment. He used an *intense* B_1 field, such that the monitored line was

Figure 2 Spin tickling of protons in 2-bromo-5-chlorothiophene. The zero-beat pattern (b) indicates where the B_1 observing field sweeps through the fixed B_2 irradiation field. Note that one of the new doublet splittings is poorly resolved (progressive case) and the other is well resolved (regressive case). (Reproduced from Freeman and Anderson¹⁴)

saturated. When B_2 was swept through a connected transition under adiabatic fast passage conditions, there was a sudden population inversion which was picked up on the monitored line as a 'transient nutation' having a very characteristic pattern.¹⁷ A progressive transition gives a positive-going oscillation whereas a regressive transition gives a negative-going oscillation. Figure 3 shows an example from the 60 MHz proton spectrum of the three-spin system in 2-chlorothiophene.¹⁸

SLOW CHEMICAL EXCHANGE

Forsén and Hoffman¹⁹ introduced an entirely new application of double resonance that has assumed increasing importance over the years and is now one of the standard applications of two-dimensional spectroscopy. If two chemical species exchange slowly in comparison with their chemical shift separation, it is possible to follow the actual transfer of spins from one site to the other by labeling them with

Figure 3 The 60 MHz proton spectrum of 2-chlorothiophene (lower trace). When the constant-frequency observing field (B_1) saturates line 3 and the perturbing field (B_2) is swept through the spectrum under adiabatic fast passage conditions, the population disturbance is transferred to the connected transitions, inducing positive-going transient nutations for the progressive case (lines 5 and 14), negative-going for the regressive case (lines 1, 7, 8, and 12). (Reproduced from Ferretti and Freeman¹⁸)

Figure 4 Simulation of the effect of inverting the spin population of a site A when there is slow chemical exchange with site X. Inverted spins are carried from A to X, reducing the intensity of the X spin signal. At later times, spin-lattice relaxation returns the populations to Boltzmann equilibrium

a population disturbance. Forsén and Hoffman used selective saturation, but it is more convenient to employ a population inversion brought about by a selective 180° pulse. A sudden population inversion of site A gives an inverted NMR signal for A and then a gradual loss of intensity at site X, as inverted spins are transferred from A to X. Later, spin-lattice relaxation returns the intensity at both sites to normal (Boltzmann equilibrium). Analysis of the time development of the A and X intensities gives the rate of chemical exchange. Figure 4 shows a simulation of the time-dependence of the A and X signals for this experiment.

NUCLEAR OVERHAUSER EFFECT

When the Overhauser effect²⁰ was first predicted, many well-known magnetic resonance scientists were reluctant to believe that such a large NMR signal enhancement could be achieved by saturating the electron spin resonance. It

was soon demonstrated by experiment. The analogous effect between two dipolar-coupled nuclear spins is much smaller in magnitude, being given by the formula:

$$S_Z/S_0 = 1 + \eta = 1 + 0.5\gamma_I/\gamma_S \quad (1)$$

where γ_I and γ_S are the gyromagnetic ratios of the irradiated spin and the observed spin, respectively. Thus for proton–proton interactions ($\gamma_I = \gamma_S$) the maximum enhancement is 50%. The full effect is only observed if the S spin relaxation is exclusively determined by dipolar interaction with the I spin. This is hardly a method for sensitivity enhancement but it has proved extremely useful as a diagnostic of proximity, since the nuclear Overhauser effect (NOE) falls off as the inverse sixth power of the internuclear distance. The early experiments were performed by selective double resonance and were usually aimed at determining molecular configuration.²¹ More recently, two-dimensional methods²² have been used to extend NOE measurements to biological macromolecules where there are literally thousands of protons exhibiting dipolar interactions, each observed Overhauser enhancement imposing a ‘distance constraint’ on the structure.

BROADBAND DECOUPLING

When the technology became available to study carbon-13 spectroscopy in natural abundance, it became clear that there was a considerable advantage to be gained by proton decoupling. First of all, this greatly simplified the carbon-13 spectrum and gathered the multiplet intensities into single lines. Secondly, it gave up to a threefold enhancement of sensitivity through the nuclear Overhauser effect. To be generally applicable, this required *broadband decoupling* in which all protons were effectively decoupled, independent of their chemical shifts. Richard Ernst provided the breakthrough with noise decoupling²³ where the second radiofrequency source (B_2) was modulated with a pseudorandom sequence of phase inversions in order to render it incoherent. At that time pseudorandom noise generators were hard to come by, so his initial experiments used ‘random’ numbers taken from the Palo Alto telephone directory. Noise decoupling was the universally accepted method for many years. The chemist simply switched on the decoupler at the appropriate frequency (the center of the proton spectrum) and set the B_2 intensity as high as possible, compatible with an acceptable level of radiofrequency heating of the sample.

Yet there is always something slightly unsatisfactory about the application of noisy or random processes in magnetic resonance. One suspects that it might be possible to devise an ordered ‘dance’ for the spins that would be more effective than this uncontrolled jiggling motion. This concept of ‘spin choreography’ evolved from multipulse experiments in solid state NMR and from ideas current in two-dimensional spectroscopy.^{12,13} It eventually led to a method of broadband heteronuclear decoupling that was effective in high-field superconducting spectrometers, where the proton spectra span a much wider frequency range. Noise decoupling can involve excessive radiofrequency heating and can ‘cook’ some delicate

Figure 5 (a) A 180° proton pulse during the evolution period of a two-dimensional experiment refocuses the α and β carbon-13 vectors. (b) Multiple refocusing of the α and β vectors. (c) Multiple refocusing with composite 180° pulses, with no windows for free precession

biochemical materials. We lost a priceless sample of a rare snake venom neurotoxin in just this fashion.

The germ of the idea for the new decoupling methods can be traced back to some early two-dimensional experiments aimed at correlating proton and carbon chemical shifts.²⁴ To simplify these spectra and to eliminate correlations through long-range CH couplings, a 180° pulse was introduced into the evolution period so that diverging CH magnetization vectors were partially refocused. If the two carbon-13 vectors are labeled α and β according to the proton spin states, the 180° proton pulse interchanges these labels and brings the two vectors to a focus (or near-focus) at the end of the evolution period [Figure 5(a)]. The corresponding CH splitting is eliminated (or scaled down) in the F_1 dimension of the correlation spectrum.

We began to wonder whether refocusing might not be used more generally to decouple protons in conventional carbon-13 spectroscopy. This ‘spin-flip decoupling’ would employ a *repeated* train of 180° proton pulses, with the acquisition of the carbon-13 free induction decay synchronized with the focus points between proton pulses.²⁵ The scheme is set out in Figure 5(b). One could liken this to freezing the motion of a disco dancer by using stroboscopic lighting of the appropriate

frequency. The carbon spins would be tricked into ‘thinking’ that they had no coupling to protons. Unfortunately this sets a quite low upper limit on the digitization rate for carbon-13 signals and any attempts to increase the proton pulse rate soon leads to excessive power dissipation.

It was Malcolm Levitt who provided the solution to this problem. The reason we need *intense* 180° pulses is that the refocusing must be effective for all proton resonance offsets. During his first year as a graduate student at Oxford, Malcolm Levitt came up with the brilliant idea of the composite 180° pulse—a sandwich of three pulses $90^\circ(x)$ $180^\circ(y)$ $90^\circ(x)$ which automatically compensates the imperfections of the individual pulses.^{26,27} This concept has much in common with the invention of the compensated pendulum, which essentially eliminated the temperature variations of the timekeeping of mechanical clocks. With composite 180° proton pulses, refocusing of carbon-13 magnetization vectors could be achieved with far lower radiofrequency levels, and therefore at much higher pulse repetition rates. Indeed it became quite feasible to assemble the composite 180° pulses into a continuous ‘windowless’ sequence [Figure 5(c)]. This allows us the freedom to set any desired acquisition rate for the carbon-13 signal, not necessarily synchronous with the proton pulsing.

There was still a fly in the ointment. Such a long repeated sequence of pulses inevitably builds up cumulative errors, even if the individual imperfections are very small. A simple phase alternation of the 180° pulses is not effective in this situation; it merely aggravates the effects of resonance offset. It was again Malcolm Levitt who saw the solution—a ‘magic cycle’ of the form $RRR\bar{R}$ where R is a composite 180° pulse and $\bar{R}$ is its phase-inverted counterpart.

This MLEV-4 cycle²⁸ proved to be significantly more effective than the existing methods of broadband decoupling. This can be quantified in terms of a figure of merit Ξ defined as the ratio of effective decoupler bandwidth to decoupler field intensity:

$$\Xi = 2\Delta B_{\max}/B_2 \quad (2)$$

where $\Delta B_{\max}$ is the proton offset at which the carbon-13 signal falls to 80% of its maximum intensity. Noise decoupling achieves a figure of merit $\Xi \simeq 0.3$, while MLEV-4 has $\Xi \simeq 1.0$. It soon emerged that ‘supercycles’ could be designed²⁹ by combining cyclically permuted versions of MLEV-4 into a longer sequence. These more elaborate decoupling sequences have wider effective bandwidths, for example MLEV-64 has a figure of merit $\Xi \simeq 1.8$, and more uniform decoupling efficiency across the band.

There were nevertheless some disturbing features when the experimental results were examined in detail. The decoupling efficiency appeared to be very sensitive to the exact phase shift between the ‘x’ and ‘y’ pulse channels; indeed the sequences appeared to work slightly better if this phase shift was not quite equal to 90° . These and other curious new phenomena were explained by a theory advanced by John Waugh.^{30,31} Hitherto the favored treatment had been average Hamiltonian theory. The new approach considered the cyclic nature of the proton motion in the time domain and permitted a direct calculation of the form of the decoupled carbon-13 spectrum as a function of decoupler offset. Essentially this predicted a very small residual splitting of the carbon-13 line which varied

Figure 6 Off-resonance trajectories for the combination $90^\circ(x)[90^\circ(-x)]^{-1}$. Deviations due to off-resonance effects are largely compensated and the trajectories terminate near the $-z$ axis (Reproduced from Shaka et al.³³ by permission of Academic Press)

with offset. The aim was to devise a pulse sequence that made these residual splittings so small that they were always hidden within the instrument linewidth.

The Waugh theory explained why cyclic permutation and phase inversion were of paramount importance in the construction of decoupling supercycles. It also predicted that sequences involving combinations of ‘x’ and ‘y’ pulses would be particularly sensitive to the precise value of this phase shift and showed why the optimum would not be exactly 90° . At this point A. J. Shaka made a seminal contribution to the decoupling saga by inventing an entirely new family of decoupling sequences^{32,33} based on the principles laid down by John Waugh. These new sequences involve only 0° and 180° radiofrequency phases, thus avoiding the difficulties with orthogonal radiofrequency channels.

Again it was Malcolm Levitt, on a short visit to our laboratory, who suggested one of the key ideas. A 90° pulse is to some extent self-compensating, in that it brings magnetization from the $+z$ axis into the xy plane for a wide range of offsets. If this could be followed by a pulse that generated mirror-image trajectories then this would carry these vectors to the $-z$ axis, a good approximation to the ideal compensated inversion pulse (Figure 6). This may be represented as:

$$R = 90^\circ(x)[90^\circ(-x)]^{-1} \quad (3)$$

where $[90^\circ(-x)]^{-1}$ is a ‘reversed precession pulse’ about the $-x$ axis. The latter is a *hypothetical* pulse for which resonance offset acts in the opposite sense to Nature. Now the combination $270^\circ(-x)270^\circ(x)$ is a close approximation to an exact cycle. We may write this as

$$270^\circ(-x)270^\circ(x) \approx E \quad (4)$$

where E is the identity operation. Malcolm Levitt suggested that this implied

$$180^\circ(-x)270^\circ(x) \approx [90^\circ(-x)]^{-1} \quad (5)$$

that is to say we have a practical way to implement the hypothetical 90° reversed precession pulse. The compensated 180° pulse would then be

$$R = 90^\circ(x)180^\circ(-x)270^\circ(x) \quad (6)$$

This may be written in the shorthand notation $\bar{1}\bar{2}\bar{3}$, where '1' represents a 90° element and the overbar a phase inversion. Assembling four of these elements in the sequence $RRR\bar{R}$ gives the decoupling scheme $R = \bar{1}\bar{2}\bar{3} \bar{1}\bar{2}\bar{3} \bar{1}\bar{2}\bar{3} \bar{1}\bar{2}\bar{3}$. This was given the acronym WALTZ-4. Expansion of this sequence through cyclic permutation of a 90° element followed by global phase inversion generates the supercycle WALTZ-16. This widely used decoupling sequence, which has a figure of merit $\Xi \simeq 2.0$, involves much smaller residual splittings than WALTZ-4, and is user-friendly since it is relatively insensitive to pulse miscalibration and to errors in the radiofrequency phase shift.

In certain situations, for example at very high fields or in experiments where carbon-13 (or nitrogen-15) has to be decoupled during proton observation, even broader decoupling bands must be covered. This may be achieved by slightly relaxing the demand for extremely small (unresolved) residual splittings. It is then possible to design sequences, for example GARP,³⁴ with a figure of merit as high as $\Xi = 4.8$.

CONCLUSIONS

Double resonance thus covers the entire range from extremely weak irradiation fields that are just sufficient to burn a hole in a single line, to intense, broadband irradiation that affects all the spins of a given nuclear species, irrespective of chemical shift. Most double resonance applications described above—assignment, correlation, decoupling, chemical exchange, multiple quantum effects, nuclear Overhauser enhancement—are now carried out by multidimensional spectroscopy, although the basic principles remain the same.

Fujiwara, Shizuo: Early Development of the Study of NMR in Japan

Shizuo Fujiwara

The University of Tokyo, Urawa, Japan

NMR studies in Japan were begun in 1951 at the Physics Department of Osaka University by Prof. Jyunkiti Itoh and his colleagues, who performed structural analyses of the double halides of potassium mercury chlorides and other compounds.¹ In 1952, at the University of Electro-Communications, I applied NMR techniques to the precise measurement of nuclear magnetic moments.

Soon after World War II, the General Headquarters of the Allied Armies (GHQ) strictly controlled the introduction of foreign scientific literature into the country. Under these conditions, the initial NMR studies took rather dramatic turns.

Before World War II, two groups in Japan were engaged in nuclear science research using cyclotrons, one at Osaka led by Prof. Seishi Kikuchi, and the other at RIKEN, the scientific research institute in Tokyo, led by Dr. Yoshio Nishina. These two cyclotrons were destroyed by GHQ when the war ended. However, Japanese scientists remained hopeful of continuing the study of nuclear science.

The physicists at Osaka University learned about the discovery of NMR because the library of the American Center in Osaka was located in the building next to the Physics Department. When Dr. Itoh and Dr. Teinosuke Kanda read Purcell's paper, they began their own investigation of NMR with the encouragement of Prof. Kikuchi.

I learned about NMR through a conversation with a classmate who was working for the US Army as a translator. At that time, I was working on high-frequency chemical analysis.² He told me that US scientists had discovered a method of measuring nuclei by radio waves, and I realized from the US discovery that I should incorporate a magnetic field into my high-frequency chemical analysis. Therefore, without any written guidelines, I constructed an NMR spectrometer. The aim was to apply nuclear measurements to the field of analytical chemistry. The entire spectrometer, including the electromagnet, was handmade. I received considerable guidance on instrumentation from Mr. Shoichi Hayashi and on theory from Dr. Kenjiroh Kambe.

Hayashi and I could measure nuclear magnetic moments very precisely by using a standard wave of 100 kHz; at the time the Japanese Government encouraged scientists to use a standard wave in all studies involving radiofrequency techniques. Thus, we obtained very accurate nuclear magnetic moments for the nuclei ^1H , ^{19}F , ^{23}Na , ^{63}Cu , ^{65}Cu , ^{79}Br and ^{81}Br .³ Because the US did not have good data on copper, our data were registered at the Oak Ridge National Laboratory.⁴ Meanwhile, in 1954, a paper by Profs. Ryogo Kubo and Kazuo Tomita was well received by NMR researchers as a broad outline of NMR dynamics.⁵

I went to the laboratory of Prof. H. S. Gutowsky at the University of Illinois in 1953 for further study of high-resolution NMR. While there, I participated in the construction

of a high-resolution NMR machine. It used a permanent magnet and operated at 28 MHz. In January 1955, good resolution was obtained, largely due to the new technique of sample spinning. At the suggestion of Prof. Gutowsky, I tried to determine whether the proton signal of monofluorobenzene showed a composite multiple structure. Prof. Gutowsky was particularly interested in obtaining information about the localization of π electrons in aromatic rings in connection with the molecular orbital theory of Prof. Mulliken of the University of Chicago. The spectrum obtained at that time showed a simple doublet structure.

I returned to Japan in October 1955. With the warm approval of Prof. Gutowsky, I constructed a duplicate of the NMR machine at Illinois using research funds from the Japanese Ministry of Education. With Mr. Hiroshi Shimizu, I remeasured the NMR spectrum of monofluorobenzene and obtained a spectrum with a multiplet structure, which suggested a localized π -electron distribution. The spectrum was quantum-mechanically analyzed as an $\text{AB}_2\text{C}_2\text{X}$ system. The results of the analysis gave nonuniform distributions of the π electrons at the *o*-, *m*-, and *p*-hydrogens. Furthermore, the data showed that the resolution of our machine was about 0.2 Hz, as compared with that of the Illinois instrument of ca. 0.5 Hz. For the analysis of the spectrum, we used the Parametron computer, PC-1, at the University of Tokyo. Unfortunately, publication of our results was delayed,⁶ and thus did not contribute directly to the growth of molecular orbital theory.

The first NMR meeting sponsored by the Chemical Society of Japan was held in the fall of 1960 in Tokyo. I am pleased to have organized the First International Conference on NMR in Tokyo in 1965. Among the participants were such pioneers as Drs. E. R. Andrew, S. Alexander, J. Baldeschwieler, A. L. Bloom, R. R. Ernst, R. Freeman, D. M. Grant, H. S. Gutowsky, O. Jardetzky, W. D. Knight, G. E. Maciel, L. W. Reeves, C. Reilly, R. U. Lemieux, M. T. Rogers, J. N. Shoolery, C. P. Slichter, J. S. Waugh, and others from abroad, as well as Drs. J. Itoh, K. Kambe, Y. Kakiuchi, T. Kanda, R. Kubo, K. Tomita, and others from Japan. This conference was the first international meeting in which physicists and chemists, both theoreticians and experimentalists, could interact. Subsequent meetings in this series led to the formation of the International Society of Magnetic Resonance, which continues to hold meetings every three years.

The Japan Electron Optics Co., JEOL, was founded in 1947 by Mr. Kenji Kazato to develop electron microscopes. When I returned home in October 1955, JEOL was just starting the development of an NMR machine, and an active interest in NMR was growing in Japan. JEOL built a 32 MHz machine with an electromagnet in 1956, and then developed 40, 60, 100, and 90 MHz machines. The all-transistorized product JNM-C-60HL and later the minisized 'Minimer' JNM-MH-60 and MH-100 were welcomed by users worldwide. The MH-100 received the IR-100 award from the *Journal of Industrial Research* in 1967.

Meanwhile, the introduction of Varian and Bruker spectrometers, initially continuous wave and later using the Fourier transform mode, contributed greatly to the development of NMR in Japan. Tom Farrar and Gary Samuel played key roles in designing and constructing the first FT NMR machine in this country. Rapid scan correlation NMR spectroscopy was described by Ted Becker on a visit to Japan in 1974. Prof.

Yoji Arata and Dr. Hiroshi Ozawa quickly developed a similar system, which resulted in a productive activity in NMR and led to the currently available 60 MHz Hitachi rapid scan correlation instrument.

Since the 1960s an active interest has grown in Japan as in other countries in the application of NMR in bioscience, and in 1978 I organized the 9th International Conference of Magnetic Resonance on Biological Systems (ICMRBS) in Nara.

I began NMR and ESR measurements on the whole bodies of live silk worms in 1969⁷ and gave a detailed report at the Seventh International Conference of MRBS in New York in 1973.⁸ That work represented the beginning of the gross study of live samples in Japan. Dr. Findeis of NSF then invited me to speak in Washington DC, and I told the audience that I would like funds to construct an NMR magnet that could encompass an entire human body. In May of that year Professor Lauterbur told me that he could obtain the funds, which pleased me greatly. At that time the state of the art of computer science in Japan was insufficient for the study of imaging. Today, however, both NMR and ESR imaging studies are flourishing in Japan, as they are in the rest of the world.

It has been extremely gratifying to be involved in the field of magnetic resonance since its beginnings.

Post-doc at University of Illinois (1953–55) with Prof. H. S. Gutowsky. Professor of Analytical Chemistry University of Tokyo (1960–81). After retirement, Chemistry Professor at Chiba University, founding Dean of Faculty of Science, and founding Director of Research Institute of Information and Knowledge of Kanagawa University, Approx. 500 publications. Present research interest: origin of chirality, oxygen complex with an eutectic compound of sodium chloride and water.

Gadian, David G.: From Brawn to Brain

David G. Gadian

Institute of Child Health, London, UK

Towards the end of my undergraduate course in physics, my attention naturally focused on potential topics for a doctorate. I was interested in applying my physics in the biological sciences, and it was fortunate that the head of my Oxford college was Rex Richards, who had recently moved his NMR group from the Department of Physical Chemistry to the Biochemistry Department. Despite knowing little about NMR, and even less about biochemistry, I joined Rex's group in October 1971. This, it turned out, provided a wonderful opportunity to participate in a multidisciplinary research program, for strong links had already been forged with the biochemists, and in particular with George Radda and his group.

My D.Phil. research in Oxford proceeded in fairly typical fashion. I learnt a lot, I enjoyed the research, and for two years I produced little in the way of publishable material. But in those days there seemed to be relatively little concern about publications. My research was concerned primarily with ^{31}P spectroscopy of the glycolytic enzyme phosphoglucosmutase, and the work went reasonably well, albeit with little in the way of excitement. I showed that it was possible to assay the enzyme by monitoring the ^{31}P signals of substrate and product (glucose 1-phosphate and glucose 6-phosphate). However, this did not seem terribly exciting either, as the enzyme could be assayed rather more cheaply and with a great deal more sensitivity using standard biochemical techniques.

Then, close cooperation and discussion between Rex's and George's groups led to a series of seemingly logical developments. We showed that we could use ^{31}P NMR to monitor enzyme-catalyzed reactions not just in the presence of a simple enzyme but also with multienzyme systems, in particular in the presence of glycogen particles and muscle homogenates. It was not very long before we showed that we could detect metabolites in intact muscle (see *Hoult, D. I., Biomedical NMR Instrumentation—A Personal Viewpoint*, for further memories). The excitement was high (although I was perhaps a little too young and naive to appreciate many of the potential implications), publications ensued, my D.Phil. thesis was a lot more interesting than it might have been, and I stayed on for postdoctoral research . . . for a further eight years! During this subsequent period, the group attracted numerous talented scientists. I had a memorable collaboration with Doug Wilkie and Joan Dawson of University College, London, and many young(ish) scientists joined from overseas, including Alan McLaughlin, Pieter Cullis, Bob Balaban, Jo Ackerman, Richard Briggs, Keith Thulborn, Craig Malloy, and Axel Haase. Surface coils evolved, clinical spectroscopy emerged, and I believe that these developments, many of which in retrospect seem so obvious, reflected the unique nature of our team: namely the close liaison between physicists, chemists, biochemists, and physiologists, who may have regarded each other with some suspicion at times, but who worked on an equal basis with a high degree of mutual respect for each other's talents and knowledge.

In 1983, I moved to London to set up a new group at The Royal College of Surgeons. I was keen to establish a similar type of multidisciplinary environment, and while I do not have the space to dwell on this in any detail it is a great pleasure to see how the team has developed and progressed. Our team of basic scientists has now become the Royal College of Surgeons Unit of Biophysics, based at the Institute of Child Health and Hospital for Sick Children, Great Ormond Street, and it is good to see the basic scientists working together with clinical teams, using both imaging and spectroscopy to understand more about brain function and dysfunction, and to see how these NMR methods can now contribute to the clinical management of children with brain disease. It is also gratifying to see the increasing interaction of imaging with spectroscopy; for example, the close relationship between changes in diffusion-weighted images and energy metabolites in acute stroke models opens up the possibility of visualizing the effects of energy failure in stroke patients with the spatial resolution of imaging, rather than the much coarser resolution of spectroscopy. And the excitement continues! While we were certainly not the first to carry out functional magnetic resonance imaging of the brain, it was nevertheless a remarkable experience when we first saw regions of the brain 'light up' in response to visual and motor tasks. It was even more remarkable when we found that we could use functional magnetic resonance imaging to visualize seizure activity in a child with epilepsy, a study that I am sure we shall look back upon with a great deal of satisfaction.

These are some highlights. But of course there have been some difficult times; there have been times when experiments have failed. There was the time when, during the course of my D.Phil. research in Oxford, I was 'baby-sitting' the magnet over the Christmas period and, to my horror, I came in one morning to see it iced up. It wasn't long before I discovered that it did not attract the metal rule in quite the usual fashion, and that it had quenched because I had forgotten to switch off the power supply to the superconducting shim coils (we were having problems with the shimming) and as a result the cryogenics had boiled off. I was really depressed. I remember telephoning my girl friend Rosemary and saying to her that I might just give up science altogether and become a crofter in Scotland. But Rex knew the magnet well. He came in, dismantled the cryogen system, discovered that one of the superconducting shim coils was not wired up correctly, and a couple of weeks later the magnet was working better than ever before. And within two months, we used the magnet to obtain the first high-resolution spectra of intact tissue!

Research interests: development and application of magnetic resonance techniques for noninvasive investigation of brain metabolism and physiology.

Garroway, Allen N.: Origins of MRI—A Personal View

Allen N. Garroway

Washington, DC, USA

This is a narrow view of the origins of magnetic resonance imaging (MRI). In retrospect, I see substantial but unheeded foreshadowings of NMR imaging in my own professional education. I obtained my Ph.D. in condensed matter physics at Cornell University. Before beginning their research, physics graduate students at Cornell University would sign up for Physics 510, an advanced physics laboratory. One purpose of this course was to provide experimental physicists with a flavor for different disciplines. To this end, there were brief tours to various research groups at Cornell. I clearly recall the demonstration given by Professor Robert M. Cotts. He asked for a volunteer from the assembled Physics 510 students to stick a finger into the Varian wideline NMR probe so that the spectrometer could be tuned on the hydrogen resonance of the water in the finger. Of course, none of us stepped forward: there was no telling what those magnetic fields, both dc and rf, might do to the human body.

A 1966 summer job with Dr. Larry Bennett at the National Bureau of Standards (now the National Institute for Science and Technology) further introduced me to NMR and I subsequently joined Professor Cotts's NMR group as a research assistant in 1967. My thesis work involved the nature of concentrated metal–ammonia solutions. By determining the respective self-diffusion coefficients for hydrogen and the alkali metal nuclei with the pulsed magnetic field gradient methods of Stejskal and Tanner, we established that, over the timescale of the diffusion experiment, lithium is solvated by four ammonia molecules, while sodium is solvated by six molecules in these concentrated solutions.

Calibration of the strength of the magnetic gradient pulse is central to accurate determination of diffusion coefficients. Techniques that were well known in this field and used in our lab included measuring the time of the 'zero crossing' of the proton free induction decay (FID) of a test tube of water in the presence of a gradient perpendicular to the axis of the tube; I believe this was first reported by Herman Y. Carr. It was well appreciated that the Fourier transform of the spatial profile gave the FID, and vice versa. And, of course, all our discussions of the method of pulsed gradient diffusion measurement invoked the physical explanation that 'the magnetic gradient labels the spatial position with the frequency variable'. Still, the potential of NMR imaging was not clear in my mind.

I recall when Dr. Raymond Damadian's 1971 *Science* article¹ appeared on the determination of spin–lattice relaxation in cancerous growths. I was rather perplexed at the paper's unphysical assumption that the complex relaxation behavior of a heterogeneous tissue could be characterized by a single T_1 value. At the time, I did not foresee the potential for in vivo measurement.

In February 1972 I joined Dr. Peter Mansfield's group at Nottingham University as a postdoctoral fellow. I was

interested in the multiple pulse line-narrowing techniques that he was developing to suppress the dipolar coupling in strongly coupled homonuclear systems so that the more subtle effects of the chemical shift could be recovered in solids. In the group at that time were research students Denis Stalker and Peter Grannell. Grannell continued in the group as a postdoc, working on resolution and signal enhancement methods for NMR observation of rare spins in solids.

One day, in the early summer of 1972, as Grannell and I were having morning coffee in the Physics tea room, Peter Mansfield pulled up a chair and said, in essence: 'I've had this really crazy idea. It seems that one could measure atomic separations in crystalline materials by imposing a magnetic field gradient and observing the resulting NMR diffraction pattern'. Grannell rolled his eyes. From my experience in pulsed gradient diffusion, I volunteered that the required magnetic gradients would need to be immense and, further, that the alignment and the perfection of the crystal would need to be of the order of crystal lattice dimensions. I may have also suggested that the basic idea of using a gradient to obtain spatial information had already been demonstrated. We three batted ideas around for a while. When I returned at tea time, Mansfield and Grannell were still in extended conversation.

Mansfield and Grannell vigorously pursued this diffraction idea. However, Grannell's 'rare spin' spectrometer was not appropriate to demonstrate NMR diffraction. So Stalker, Grannell, and I performed a rudimentary 'imaging' experiment illustrating the aspects of diffraction. We imaged not a liquid but rather a solid, camphor—a plastic crystal in which intermolecular proton dipolar couplings are attenuated by rapid molecular reorientation. We employed one of Mansfield's line-narrowing sequences, now called MREV-8, to reduce dipolar couplings, and displayed the one-dimensional interferogram (pseudo FID) of a series of slabs of camphor to a resolution better than 1 mm.

That first Nottingham imaging work² was presented in a talk by Peter Mansfield at the First Specialized AMPERE Colloquium in Krakow, Poland, in August 1973. While I was sitting in the back row with Peter Grannell during that talk, the pieces finally fell into place for me, and in that epiphany I saw that magnetic resonance imaging was indeed going to impact medical science.

After Mansfield's AMPERE talk, a questioner from the audience, Professor John S. Waugh of MIT, asked if this approach was related to Professor Paul C. Lauterbur's (State University of New York at Stony Brook) 'zeugmatography' just reported in *Nature*.³ At the time none of us had seen that work. I seem to remember that Waugh in his remarks alluded to a 'zeitgeist': when ideas are 'ready', they seem to spring spontaneously and independently from many sources.

On their return to Nottingham after the Krakow meeting, Grannell and Mansfield continued their imaging work while Stalker and I pursued understanding the limitations on the experimentally obtained resolution in the line-narrowing experiments. In February 1974 some of us physics postdocs took a short holiday to Moscow. On the trip was my friend Dr. Waldo S. Hinshaw, at the time a postdoc with Professor E. Raymond Andrew at Nottingham. Hinshaw and (the late) William Moore had just returned from an ISMAR (International Society for Magnetic Resonance) meeting in Bombay and, on hearing Lauterbur's presentation there, were fired up about the prospects for NMR imaging. In my talks

with Hinshaw in Moscow, I too became more interested in imaging.

Back at Nottingham I thought further about the possibilities of NMR imaging and realized it could be used to image flow fields in liquids, both the spatial variation of the velocity field and also the velocity distribution function. One simple imaging demonstration^{4,5} I first presented at the 1974 AMPERE meeting in Nottingham showed the parabolic profile expected for laminar flow in a cylindrical tube. I destroyed magnetization in a restricted region with a $\pi/2$ pulse and then waited a further time before 'imaging' with a magnetic field gradient perpendicular to the tube axis. This way one sees signal only from the fresh spins that move into that region; the number of fresh spins and hence their signal is proportional to the local velocity in the laminar flow field.

In that flow experiment, the region was restricted quite crudely: I wrapped copper foil around the tube to (somewhat) shield those regions from the rf field, and left unwrapped the region of the tube to be interrogated.

Were there any better ways to excite spins in one region of space and leave others unperturbed? I had just read of the method of 'selective irradiation' by Tomlinson and Hill⁶ that used weak pulses to excite only a part of an inhomogeneously broadened line. I realized that such a method could then be used in NMR imaging to excite only a portion of the overall sample, inhomogeneously broadened by the applied magnetic field gradient.

I immediately implemented such a selective irradiation approach on our line-narrowing spectrometer, a homebuilt system operating at a proton frequency of 9 MHz (!) controlled by a Honeywell 316 computer with 4 K [sic] of memory. (Within this 4 K of memory, I could generate rather elaborate multiple pulse sequences, acquire up to 1 K of data, and perform a 1 K fast Fourier transform.)

My naive notion was to define a region by applying a pulse sequence that was essentially the Fourier transform of the desired region. This is not a bad approximation provided the effective nutation angles are less than $\pi/2$. I wrote a machine language program to Fourier transform an arbitrary spatial profile, and then to generate automatically the machine language code that provided the correct pulses and delays to the transmitter.

I was extremely pleased with those first results,⁷ showing a narrow selectively irradiated slice excited from the semicircular profile of a test tube of water, the same geometry I had used at Cornell to measure magnetic field gradients for the diffusion measurements.

Just as I was doing these selective irradiation experiments, Mansfield and Grannell had some imaging experiments they wanted to try out on the 9 MHz spectrometer. Indeed they had also realized that some sort of spatial restriction was quite useful if one wished to image a fully three-dimensional object. Their approach was to use saturation methods, i.e. a train of weak pulses, to destroy magnetization in unwanted regimes in contrast to the selective excitation.

Grannell, Mansfield, and I recognized we were all taking the same basic approach to slice up an object for imaging. That approach⁷ which we pioneered, selective rf irradiation to excite specific regions of a sample, finds substantial application in modern MRI.

I left Nottingham in October 1974 for a postdoctoral position at the Naval Research Laboratory. After Nottingham's initial demonstration on solids imaging, almost everyone moved to the medical applications. In the 1980s I elected to explore further some aspects for NMR imaging in materials with possible applications to nondestructive evaluation of polymeric systems. My colleagues and I at the Naval Research Laboratory continue to maintain that general interest: perhaps Mansfield's initial crazy notions about solid state imaging were not so crazy.

Here I have conveyed only my own first-hand perspective of the very early work at Nottingham; I have not described the many significant contemporaneous contributions of others. I feel a great kinship to co-workers at Nottingham and to other early workers at Stony Brook, Aberdeen, and Zurich.

There are also lessons that one might draw from these early days of MRI about the convoluted way that new ideas spring forth when the time is right; how new ideas are implemented; and how, or indeed whether, that evolution can be 'nurtured', 'managed', or 'programed' by beneficent funding organizations. But that is another topic.

Gerstein, B. C.: The Vaughan Days, CRAMPS, and Transient Techniques in NMR

B. C. Gerstein

Ames Laboratory of Iowa State University, Ames, IA, USA

I want to share our experience with the development of high-resolution solid state NMR of strongly homonuclear dipolar coupled solids. Necessarily, a large part of this history will involve Bob Vaughan.

My training in chemistry was as a low-temperature thermodynamicist. We were interested in linear magnetism in inorganic solids as studied by low-temperature initial susceptibilities, and low-temperature heat capacities. It became clear early on that the number of interesting problems in that field was too limiting for my taste. About 1970 I became interested in heterogeneous catalysis. I sought a faculty improvement leave from Iowa State University at a location where I might learn something of catalysis and the most modern techniques which could be used for such studies. I contacted Harry Gray at Caltech, and he recommended 'a really bright new chemical engineer, who is using this new solid state NMR multipulse business to look at catalytic processes.' This was Bob Vaughan, whom I called, and asked if he would consider having a senior (I was 39, and Bob 30) person working with him for a year. Bob, who did an enormous amount of traveling, replied that he would like to stop and visit my laboratory. He wanted to see, I suppose, if this fellow Gerstein was someone who had fallen asleep, or someone who could fit into his dynamic new research effort. After visiting my laboratory, he made a positive decision. He called me from Caltech saying that George Hammond had arranged half salary for me (my university covered the other half), and I could come the next year. I said 'Bob, I hope you realize that I want to come and learn your new technique, steal it, and bring it to Ames'. He said 'come along!'

It was a strange, tense, and exciting year. Bob took quite a chance in allowing me to come and work with him, his first graduate student Loren Schreiber, and Won-Kyu Rhim, a former postdoc of John Waugh's, then a scientist at JPL. Bob was a dynamic, personally kind, and brilliant man. My wife and I became close personal friends with Bob and Sharon.

Bob's NMR was homebuilt around a 1 T old Varian iron core magnet. A PDP-11, with paper tape feed for the programs, was used for experimental control, and manipulations of data. My first day in the lab was spent in replacing the Variac in the power supply of the magnet, Bob and I working and sweating together in the August heat of Southern California to pull the heavy beast from the frame, and replace it with another Bob had saved from an old supply. I rapidly realized that in Vaughan there existed a remarkable combination of chemical physicist, chemical engineer, electrical engineer, and mathematician.

Work in the Vaughan lab went on seven days and seven nights a week. I generally took Sunday off to be with my

family in Santa Monica, jogging there, or racing a Thistle Class sloop down at Balboa with three of my five children as crew. They ranged in age from 9 to 11, and together all four of us weighed a whopping 350 pounds, considered a very light crew for a Thistle. We did very well in light air.

I could always depend on Bob being in the lab any evening of the week. He would generally arrive about 8.30 a.m., and was there when I ran out of steam about midnight. When I would say 'Bob, I have to go home, I'm making too many mistakes,' he would reply 'Oh, you've had a long day. Let's quit for the night', and after I left, he went home and prepared lectures until well into the early hours of the morning. I guess he slept about five hours a night.

During that year the MREV-8 sequence was developed in the Vaughan lab (as well as earlier in Peter Mansfield's laboratory at Nottingham, although I didn't know of it at the time), and I had the marvelous opportunity to use it for the first time to determine the shielding tensor of the protons in trichloroacetic acid. I can't count how many times that probe was disassembled, a fried resistor or capacitor replaced, and reassembled, but it was enough to give me the confidence that I could go home and build a machine like Bob's, with the circuit diagrams Bob gladly supplied me, and John Yehle's kind help.

Another important feature of that year was the Vaughan group weekly seminars. During these, by either Bob or Won-Kyu Rhim, the theory behind the homonuclear decoupling experiments was developed, and I had my first taste of average Hamiltonian theory. The real beginnings of my understanding of the formalism began one weekend near the end of my stay at Caltech when my wife and I, and Bob and Sharon took a trip down to San Miguel, a little fishing village just north of Ensenada. I vividly recall my being confused about how spin operators transform under rotations. While Bob and I were walking on that marvelous six mile long sparkling sand beach just south of Ensenada, Bob said, 'no, you have to remember the order', and in the sand with his finger he traced

$$\hat{\mathcal{H}}_{\text{int}} = U_{\text{rf}}^{-1} \hat{\mathcal{H}}_{\text{int}} U_{\text{rf}} \quad (1)$$

and then pointed out that the inverse rotation operator is a product of the inverse rotation operators in inverse order. For the first time I began to see how Bob and Rhim were thinking about the design of pulse sequences, and how one might, in principle, come up with a MREV-8 oneself. Of course there are quite formal general ways of thinking about this matter that Peter Mansfield had published, of which I was not aware at the time. During the Vaughan group seminars, I took careful notes, worked them up immediately after each lecture, and consulted Bob, who was always available when questions arose. I began to appreciate the beauty of what we were doing, in that there was so tight a connection between theory and experiment that an idea conceived one day could be verified by experiment the next. Such was the case with second averaging the chemical shift by an offset¹ that Vaughan and Dybowski published shortly thereafter.

Regarding Dybowski, that winter Bob brought me a file of an application for a postdoctoral position from this fellow Dybowski, who did his graduate work with Wade at the University of Texas. It was characteristic of Bob that he sought advice from a wide range of people, and he asked me to look carefully at the file, and help him decide if we should have

him in the group. Dybowski's file looked pretty good to me, even though a 6 ft. 2 in. Texan with flaming red hair and a ponytail seemed a bit strange at first sight. Dybowski arrived in the spring, and he and I became fast friends as I quickly realized he was a superb chemical physicist with a fine pair of hands, and a lover of Mexican food. We both gained quite a bit of weight that summer as we toured the restaurants, especially 'Ernies' in Pasadena.

In September of 1973 I returned from Pasadena, and proceeded with the help of ISU's Ames Lab electronics' shop to recreate Bob's pulse spectrometer, incorporating state-of-the-art improvements in the pulse programmer as devices came on the market. We had an old 1 T Varian electromagnet like Bob's, donated to Iowa State by Dow Chemical, which was used by Baker and Burd for their pioneering field/frequency locked spectrometer and for Baker's early INDOR experiments. A very bright young electrical engineer named Doug Adduci was assigned to help build the pulse programmer, and with the advent of microswitches and Merrimac adjustable phase shifters, we were able to create a four phase rf switch with 25 possible pulses on which our first homonuclear decoupling pulse experiments were made. The Vaughan group rf switch employed picturesque sliding trombone phase trimmers protruding from the console like a device out of Star Wars. We lost a bit of culture when we went to the Merrimacs. Subsequently, since about that time the microprocessor was developed, Adduci designed a microprocessor-based pulse programmer² which gave us an enormous increase in versatility for that period.

I believe I had read somewhere (but I cannot trace the source, although John Waugh tells me he was aware of the idea at the time⁹) that magic angle spinning might be coupled with homonuclear pulse decoupling to produce liquid-like lines of protons in strongly homonuclear coupled solids. Perhaps the idea came from Ray Andrew's papers in which he said that both shielding anisotropy and homonuclear dipolar coupling could be removed by magic angle spinning. In any event, we proceeded to review the techniques of Jesse Beams which he used in his collaboration with The Svedberg on the ultracentrifuge to make high velocity rotors. I blush to admit that our first rotors were made of phosphor bronze. A graduate student named Lorenzo Ryan, who visited me from Arizona when I was at Caltech to see if he wanted to work with me at ISU, was working on getting the MAS going. He used ideas from the papers by Andrew and by Lowe, and referred back to Beams's RSI paper that was published the year I was born. We could spin a Kel-FTM DuPont rotor of Beams's design to a kilohertz or so, but no more. A personal call to Beams resulted in the use of a ballast volume to take the surges out of our compressed air line, and a speed of 3 kHz on a good day.

A postdoctoral student by the name of Chee Chow, who had worked with Rog Willett at Washington State, had just come to work with me. We had found an old Rhodes-Schwartz tube type frequency synthesizer in a scrap heap in the Physics Department at ISU, and used it to obtain our first NMR signals. A retired IFI 500 distributed amplifier system, used previously by Gerry Pearson on ENDOR experiments, was the transmitter. Chow was a bit wild, and when resonance could not be found at one frequency, he began varying the frequency all over the ball park, resulting in the Lowe-Tarr scheme quarter-wavelength stubs which protected the receiver failing to do so, and the first two Avantek amplifiers in the receiver were 'fried'

as Vaughan would say. It was a fortunate accident. When Doug Adduci heard of our tragedy, he asked me if I was interested in rapid recovery. 'YES!', I replied. Doug had just seen an ad for Spectrum-Microwave receivers that boasted a 1 μ s recovery after a 5 V overload. With these, and with Dave Torgeson and Doug's careful design of the receiver chain,³ we were able to obtain a recovery of less than 2 μ s after a 500 W pulse at 56 MHz, and a cycle time for the MREV-8 sequence of about 22 μ s on a good day.

One event that made the construction of our spectrometer possible was that the State of Iowa had funded ISU for \$5 million to study coal cleaning. Iowa has lots of coal, but much of it is high sulfur content, some as much as 15% due to chunks of pyrite as large as my fist. The Ames Laboratory Director at the time, Bob Hansen said 'Bernie, why don't you apply for some of those funds and see if this new technique you have a gleam in your eye for can do some new analysis on coal?' We obtained enough to buy our first PRD frequency synthesizer, and our first publication using NMR was on the nondestructive determination of hydrogen in coal.⁴

By that time, Rich Wilson had come from Rollie Myers' group at Berkeley as a postdoctoral, and Bob Taylor, Bob Pembleton, and Lorenzo Ryan were students. One winter morning in 1976 was posted on my door the first CRAMPS⁵ spectrum obtained in our group. Our CRAMPS paper was published the next year, with Ryan coining the acronym, inspired by Alex Pines' use of his name in one.

Of course, at the same time, in Jena, Hans Rosenberger and Gerd Scheler were working on the same technique with similar success in the more difficult higher frequency region using superconducting magnets. I had the pleasure of visiting their lab during the trip to Poland in 1983 for the symposium Alex Gutsze organized on 'NMR in Surface and Colloid Science'. That was the trip during which I was arrested for being a spy, but that is another story.

Dybowski stayed at Caltech for a couple of years, and then accepted a faculty position at the University of Delaware. Before leaving Caltech, he asked me if I was interested in making a book from the Vaughan group seminar notes. I immediately sent him the first two chapters which I had written for my own group seminars, and after some agonizing collaboration at a distance we finalized the manuscript working together from morn to eve during a grueling two week stint in the Pocono Mountains. We stayed on speaking terms. 'Transient Techniques in NMR of Solids'⁶ was published by Academic Press in 1985.

I will never forget that terrible day in 1979 when Sunney Chan called me and said 'Bernie, I am afraid I have some bad news for you. Bob Vaughan was on that DC 10 which went down in Chicago on Friday.' For years after that I had dreams that Bob was still alive, and that it was all an awful mistake. I have not had one of those for a while now. We still see Sharon and her second husband when we visit California.

I must also mention the enormous contributions made to our group by Paul Murphy, who succeeded in achieving our first cross polarization experiments, using a receiver that looked like a rat's nest, and had to be breathed upon properly to prevent feed-thru of the proton signal, and the subsequent applications that students such as Murphy and Po-Jen Chu made to fossil fuels, polymers, inorganic solids, and materials such as amorphous silicon hydride.

Finally there came to our group from Poland as a result of my visit there in 1983 a young man named Marek Pruski, who is presently the group leader, and deservedly so, of the research group that once I directed. Pruski, with training under Gutsze as a physicist, thoroughly modernized the equipment in the group, and with his keen criticality and marvelous creativity made our collaboration with Terry King a stunning example of the power of modern NMR in the study of heterogeneous catalysis (see Pruski, *Supported Metal Catalysts*), and is proceeding to cut his own path on the world scene of NMR.

One of the most incredible experiences I had was that of meeting Maurice Goldman in 1987. Alex Pines and I were the two Americans invited by Joseph Virlet to talk at a French NMR school in Les Houches. Alex lectured on multiple quantum NMR among other subjects, and I didn't understand it. After the lecture, I asked Maurice, whom I had admired from afar for years if he understood this subject. He said, 'I think so. Come to my room this evening'. Well, for that evening and two more, I was in Maurice's room, and he wrote with the speed of light, developing the theory of the development and detection of multiple quantum NMR in spin-1/2 dipolar coupled solids. It was stunning! The spin dynamics he carried in his head was simply a marvel to witness. He was enormously kind, and unbelievably patient with my slow understanding of his lightning-like thinking. I was on leave at that time and spent the next month enjoying Wiebren Veeman's hospitality in Nijmegen. Wiebren gave me a desk and only asked that I give his group some lectures on this theory of multiple quantum NMR, which he, as another lecturer at Les Houches, had also heard. After two weeks, I understood the production from reading Maurice's notes, and gave a three hour lecture on that. After another two weeks, and some phone calls to Maurice, I understood the detection well enough to talk about that. Dave Cory, who was a postdoc with Wiebren at the time, immediately built a probe for the experiment and proceeded to begin to try to get some multiple quantum spectra. He didn't have the capability of fast digital phase shifting which we developed after I returned to the US the next spring,⁷ but what he did with what he had was simply amazing!

After returning to the US, I wrote these lectures into what became a publication⁸ with the last truly brilliant student to work with me, Son-Jong Hwang, a three-year Phillips Fellow, and awardee of the ISU Alpha Chi Sigma award for outstanding doctoral research.

NMR has been kind to me. I have met and enjoyed the hospitality of people who have suffered through my pizza;

Cecil and Mary Dybowski, Chuck and Kim Wade, Bob and Marcia Bryant, Bob and Helene Pearson, Don and Joan Wilson, Dave and Mary VanderHart, Nino and Sue Yannoni, Gary and Maxine Maciel, Dave and Reva Grant, Alex and Dietza Pines, Ken and Christine Packer, Jose' and Carol Fripiat, Harry and Christina Pfeifer, Dieter and Crystal Michel, Jacques and Mimi Fraissard and Jacques's entire warmly hospitable group, especially Robert and Danielle Vincent and Claudine Dore'mieux-Morin, Michel and Claudette Guelton, Jean-Paul and Patricia Amoureux, Lechek and Anna Stefaniak, Bogdan Kamienski, and Alex Gutsze, only some of the many lovely people who are friends and have made life richer.

Goldman, Maurice: The Time when Spin Temperature was Hot Stuff

Maurice Goldman

CEA-Saclay, Gif-sur-Yvette, France

Spin temperature theory underwent its ‘big bang’ in the late 1950s and early 1960s. I was privileged to be at that time in one of the hot spots where these developments took place, both as a witness and a partial contributor. My view of what happened is therefore from the observation point of Anatole Abragam’s Laboratoire de Résonance Magnétique at Saclay, France.

When I joined this lab in 1956, I knew about the funny results observed by Purcell and Pound in the demagnetization/remagnetization of LiF, but my first real introduction to spin temperature was at the return of Abragam from a trip to the United States in early 1957: he had had an idea which he told us with great excitement. The slow demagnetization down to zero field in the Pound and Purcell experiment corresponded to an evolution of the spin system which was adiabatic in the *thermodynamic* sense, not in the Ehrenfest sense: it was meaningful to speak of a spin temperature which evolved from Zeeman to dipolar and whose evolution could be calculated. Thanks to the nature of the energy spectrum and the slow relaxation of the nuclear spins, this temperature could differ from that of the lattice and be either positive or negative. If this was true, the nuclear polarizations after slow magnetization should be the same whether the system in low or zero field had been cooled by adiabatic demagnetization or by contact with a helium bath. Warren Proctor, who was then visiting us, was invested with implementing the experiment, which he did successfully together with a few others, the set of which is rightly considered as a historical landmark for spin temperature. I was honored with the task of calculating the local field.

At about the same time, I read a preprint by Alfred Redfield about a slower saturation for dispersion than for absorption in copper and aluminum, together with an attempt at a physical explanation. Ionel Solomon asked me afterwards: ‘What did you get out of it?’ My reply: ‘Not much’. This could have been said by anybody else in the world (except Alfred). It was simply the discovery, in 1955, of spin temperature in the rotating frame. Most of the concepts Abragam had had the idea of were there, plus some extra, under more complex conditions. It was the great merit of Abragam to decipher this work and make his understanding of it available to the scientific community in his famous book of 1961, ‘The Principles of Nuclear Magnetism’.

After the interlude of my military service, I read this book in preprint form in the summer of 1960. All of us in the lab have had the advantage of learning there about spin temperature roughly one year before the rest of the world. Shortly after reading the chapter on spin temperature I had a bizarre idea: induce chlorine transitions in low field, in *p*-dichlorobenzene, go to zero field and remagnetize, in a cyclic fashion. I expected to get in that way a proton polarization nearly 10-times larger

than that corresponding to the Boltzmann ratio for the chlorine quadrupole splitting. I told this to Ionel Solomon, whose reply was: ‘No! All of us have been taken off-guard by Overhauser’s prediction, but now it is digested. We even understand the polarization in solids (reference to the solid effect, newly discovered by Abragam), but too much is too much, and you will never make me swallow that you can get more than the solid effect’. He turned out to be wrong. I started working on this ‘rotten’ idea with André Landesman, initially so that he could help me use a 35 MHz oscillator he had built. We saw nothing (I found the effect later, after realizing there were problems with mixing and relaxation times). One day, while rf irradiation in zero field near the quadrupole frequency of ^{35}Cl had been on, André absent-mindedly put the magnetic field on and we saw an ENORMOUS proton signal on the run. We started working feverishly to determine the qualitative features of the effect, which were surprising. Proton polarization was positive or negative when the irradiation in zero field was below or above chlorine quadrupole resonance. Solomon: ‘It’s ridiculous! When you irradiate in zero field, how do the protons know in which directions to polarize when the field is put on?’ These were exciting days where, in the rush of new exploratory experiments, we had visits from Abragam and Solomon several times a day, with frantic brain-storming sessions. It was Solomon who first got the right interpretation: it was a matter of Redfield-like spin temperature. What determined the polarization direction was the sign of the dipolar spin temperature in zero field. He extended the idea to dynamic polarization through paramagnetic impurities, and introduced the notion that the nuclear Zeeman reservoir can get mixed with the electronic spin-spin reservoir, a process distinct from the solid effect proper, which turned out to be correct and of great importance for the production of polarized targets. Alfred Redfield, who came a few months later for a one-year visit, tried to fit this with his baby, the rotating frame. It was not obvious for a quadrupole splitting and he tried to imagine a frame that would be simultaneously rotating in two opposite directions. The final answer was formulated by André and myself: forget about geometrical pictures and use an interaction representation. During the course of discussions, Alfred made several remarks which we did not understand. There are some points associated with our work we understood only about two years later, and then we realized that Alfred had understood them from the start from these remarks that had flown over our heads.

Alfred Redfield is somebody quite remarkable. In one work, described in his article of 1955, he had invented spin temperature in the rotating frame, understood sudden and fast passage, mastered the concept of local field, and derived the complete theory of relaxation in the rotating frame. In my contacts with him I have been struck by the rapidity and profoundness of his understanding of physical problems. These qualities are combined with a rare gift for obscurity. It took me a long time to understand why, until I heard him give a lecture at a summer school on his NMR work on superconductors. This talk was luminously clear! It is because he knew his NMR audience was not fluent in superconductivity. The root of his being obscure is genuine modesty: when talking NMR to a NMR man, it would be insulting to describe in too much detail what is obvious (what he thinks is obvious).

I worked for several more years alone on this subject. I had the surprise to see our first big article *Thermal mixing in low*

fields cited in a bibliographical compilation on geology (under the title *Thermal mining in low fields*). These were years of frantic experimental explosions by a small international group of spin temperature addicts to test all consequences of the spin temperature concept, both in the laboratory and in the rotating frame, and to invent new methods for the benefit of NMR in solids. To cite but a few of them: besides the gods Abragam and Redfield, there were Charles Slichter with Judy Franz, Hebel, Holton, Lurie, Schumacher, and Ailion, Erwin Hahn with Anderson, Hartmann, Strombotne, Irving Lowe, and Walter Goldburg plus S. Clough later on, Bloembergen and Sorokin, R. Walstedt, Jean Jeener with Broekaert, Eiseendracht, and Van Steenwinkel, the Soviet schools with Provotorov (about whom I will have more to say), Atsarkin, Mefed, and Rodak in Moscow, and Khutsishvili and Buishvili in Tbilissi, and, in France, Solomon and Ezratty, and Jerome in our lab, Sapoval and Lepine, Minier and Berthier, plus a number of others. Among the subjects investigated were the sudden and adiabatic variations of the Hamiltonian, the effect of pulses, the role of spin-spin interactions in cross polarization, nuclear relaxation in low field, actual or effective, all kinds of thermal mixings, cases when there are several constants of the motion, the validity of spin temperature for dilute systems of electronic spins, etc Several ideas were in the air. Once I told Abragam about an idea for detecting slow motion. He replied that Redfield had had the very same idea one year earlier, but finally the fastest on the draw were Ailion and Slichter. Likewise, Jeener and I simultaneously made similar studies on the adiabatic modulation of the local field in the rotating frame. There are other examples.

In the spring of 1962, Ionel Solomon talked at our weekly seminar about an article by Goldburg where he had found faster rf saturation off-resonance than on-resonance, in accordance with a theory of an unknown Soviet physicist named Boris Provotorov. Abragam took over to describe this theory from a preprint in Russian that this Provotorov had handed to him. It dealt with the dynamics of the establishment of a spin temperature in the rotating frame when the rf field was much smaller than the local field. The theory turned out to be fundamental for understanding CW NMR in solids. It was extended by Provotorov to cross polarization where it proved equally important. I had taken careful notes (at the date of May 28, 1962) and for a while I became the Provotorov expert in the lab, whom everybody consulted whatever his or her problem. One of them was Jacqueline Poitrenaud, who wanted to study the correlations of conduction electrons at nearby nuclear sites in metals from the ratio of Zeeman to dipolar relaxation times. The theory was from Redfield and the experimental method from Solomon and Ezratty, with lock-in signals. Her problem was that the results made absolutely no sense. I succeeded in finding out why by using Provotorov's theory to describe the saturation of lock-in signals in solids. Under her conditions (modulation period shorter than relaxation times), what she saw was not what she expected. A test of the theory was that the lock-in signals had to saturate more slowly in the absorption mode than in the dispersion mode, which she verified. I published the theory together with a simplified formulation of Provotorov's theory in French, and outside France it was virtually only noticed by the Russians. A number of other applications of the Provotorov theory of direct practical usefulness for NMR work were discovered later.

A few years later, Abragam thought of writing a new edition of his book on nuclear magnetism, not alone but in collaboration with three people in the lab: Jacques Winter, André Landisman, and myself. I would be in charge of the chapter on spin temperature. This project did not come off, and my chapter ended up as a book. At that time the cognoscenti of spin temperature were considered to be a small, exclusive (and snobbish?) club whose esoteric language was opaque to outsiders. Having experienced the usefulness of this theory, I tried very hard to be as clear as possible so as to turn the small snobbish group into a large snobbish group. It was then part of the folklore of the lab that to be exposed to explanations of mine turned anybody dizzy, and Abragam feared that I would lack clarity. He took the pain of reading each chapter several times (as many times as I rewrote them after the grinding mill of his criticisms). Really he should be considered a co-author, and in retrospect I think he was right: without him it might have been terribly obscure. I tried to follow the policy of Abragam in his book on nuclear magnetism: cite as fairly as possible the authors of what I was talking about, but avoid giving people's names to phenomena or equations. This could be considered questionable as regards Alfred Redfield, but I may possibly have been right after all. He established so many basic equations, each of which is referred to as 'the Redfield equation' in the literature, that if I had done the same in the restricted space of one or two chapters, I fear complete confusion would have ensued. I made just one exception to this rule, for Provotorov, for the following reason. At the time of sending the manuscript to the editor, I met at a congress Mrs Rodak, who told me that my article in *Journal de Physique* had been of definite help to Provotorov in dressing his theory with western respectability, at a time when some of his colleagues claimed that this theory was nonsense and he himself was insane. I decided that giving some advertisement to Provotorov in my book could do no harm.

At about the time of publication of the book, Rhim, Pines, and Waugh at MIT made their 'magic sandwich' experiment showing that after all spin temperature might not be as leakproof as then believed. John Waugh told me later he hoped I would receive the preprint while celebrating the publication of my book with a glass of champagne in hand. Firstly there was no champagne celebration, and secondly what I received was an empty envelope. John swore it was his secretary who forgot to put a preprint in it, but I keep being convinced that something Freudian must have been involved. This magic sandwich business proved important. Firstly it compelled us to re-examine critically the concept of temperature, and it proved that the concept of macroscopic irreversibility simply reflects the limitation of our means of handling of large systems, in contrast to NMR which is richer than other disciplines in that respect. Secondly, in the hands of Alex Pines and his students, it opened the way to the study of multiple quantum coherence in solids, so fundamentally and practically useful at present in NMR.

It was in 1965, while I was on a one-year visit to Dick Norberg's lab in Saint Louis, that Abragam asked me that on my return I direct an investigation of nuclear magnetic ordering (NMO) following the principle he had published: polarize dynamically the nuclei and then demagnetize them either in the lab or in the rotating frame. I started at the end of 1965 with Maurice Chapellier and a Ph.D. student, Vu Hoang Chau. Nuclear magnetic ordering had long been a dream

and a challenge, because of the extremely low temperature it required, in the microkelvin range. Thanks to Abragam's scheme, it would only be a spin temperature. We chose to work in the rotating frame where the form of the secular dipolar interactions could be modified by rotating the sample in the field, and where we could use NMR for observation. The field was entirely virgin. On the one hand we had to choose the proper system and put into it the proper paramagnetic centers so as to obtain large dynamic polarization, and on the other hand we had to learn the approximate theories of magnetic ordering so as to predict which structures would be produced with which properties. Getting help from professional theorists of magnetism proved hopeless: they lost balance as soon as did the rotating frame. The third hand was devoted to imagining which methods could be used to measure these properties. Necessity compelled us to exhibit still more hands. For the practical purpose of measuring the rf amplitude, calibrating the nuclear polarization, calibrating the receiver gain, understanding and minimizing losses due to the adiabatic demagnetization or CW signal observation, we had to rederive the whole of NMR theory so as to devise new methods and then implement them experimentally. Our previous NMR baggage which was restricted to the high-temperature approximation was of limited help. There was also the need to master cryogenics then in relative infancy, practice EPR at then indecent wavelengths, i.e. 4 mm and then 2 mm, and understand in depth (in order to tame them) dynamic polarization, electronic relaxation, phonon bottleneck, nuclear Zeeman, and dipolar relaxation at low temperature (still not understood).

We stayed in this field for over two decades, with a number of collaborators: J. F. Jacquinot, V. Bouffard, S. Cox, Y. Roinel, W.Th. Wenckebach, C. Urbina, S. Leibler, C. Fermon, J. Gregg, F. Bonamour, plus P. Roubeau for the cryogenics and P. Meriel, G. L. Bacchella, and M. Pinot for the neutron diffraction. We performed clean and elegant studies on ferro- and antiferromagnetism and rotating helimagnetism on a number of compounds: CaF_2 , LiF , LiH , TmPO_4 , KMgF_3 . We used both NMR and neutron diffraction (it was Abragam who found this was possible, against the views of all neutron specialists). I think we did a good job, but it was very difficult and the yield of results per unit time very low. Few have followed us, except Tom Wenckebach after a one-year visit to our lab. Other studies of NMO many years later were of a different nature and, although very interesting, were much more remotely connected with the NMR brand of spin temperature.

Other, more human (i.e. high-temperature) developments of spin temperature were scant during that period. They consisted mostly of checking its validity for effective Hamiltonians in multipulse sequences. Such studies were undertaken by Pines and Waugh in 1974, Rhim, Burum, and Elleman in 1976, and Quiroga, Virlet, and myself in 1982.

NMR in solids has evolved towards the generalized use of pulses, sample spinning, and Fourier transforms, with strong emphasis on physicochemical applications, and spin temperature theory has become of much more limited use than we had anticipated.

What remains is that spin temperature theory stands as a beautiful body of knowledge which gave rise to an astonishing number of diverse experiments of great elegance and of fundamental character in the general frame of

thermodynamics. What is particularly remarkable is its twofold character. On the one hand, the concept of spin temperature proves valid down to temperatures where a symmetry breaking takes place in the form of magnetic ordering, and on the other hand it can also be proved that spin systems are definitely not stochastic, through the selective refocusing of the off-diagonal elements of the density matrix by clever spin manipulations.

The historical development of spin temperature has followed the typical pattern of all scientific endeavors. Its evolution did not follow logic, complex things appeared before simple ones, and simple ones looked complicated for not being properly understood. Progress does not proceed along the majestic path of induction–deduction imagined by Descartes, but mostly through the laborious elimination of misconceptions and prejudices. The emergence of a new idea, however simple, is definitely unnatural and painful. The awareness that the theory had become mature came to me when, after reading my book on spin temperature, a Ph.D. student of mine said: 'Well, it's all evident!'

It seems appropriate, as a conclusion, to stress how incredibly lucky we have been that spin temperature theory has developed at all. There are at least two circumstances that could have caused its abortion. It was the observation that dispersion did not saturate, in contradistinction to absorption, which led Redfield to the conception of a spin temperature in the rotating frame. He worked with copper and aluminum and looked at the lock-in signals. It so happens that in these metals the relaxation times are not long, compared with the periods of the field modulations he used, and what he saw was close to the derivative of the CW steady-state signals. Had he worked with an insulator, or used a faster modulation, he would have observed the opposite: a normal saturation of the dispersion signal (at resonance) and a much slower saturation of the absorption signal. Who knows where this would have led him? The second circumstance was the discovery of the 'magic sandwich'. It seemed to disprove spin temperature at a time when innumerable experiments had already quantitatively verified its predictions. Thus, there could be no question of rejecting it flatly, but we were led to scrutinize anew the foundations of the temperature concept. The mathematical description of this experiment is extremely simple and it could have been done much earlier by anyone of the patricians of NMR. The result would probably have been that nobody would have accepted the mere idea of a spin temperature. The great merit of Rhim, Pines, and Waugh is not only to have discovered the magic sandwich, but not to have discovered it too early. To borrow an expression from Arthur Koestler, I take these as further proof that scientists are definitely sleepwalkers.

Gorenstein, David G.: Developments in ^{31}P NMR

David G. Gorenstein

University of Texas Medical Branch, Galveston, TX, USA

Unlike almost all other fields of science, the theory and application of nuclear magnetic resonance has been on an exponentially rising curve of interest for the past 50 years. ^{31}P NMR has shared similar success from the first spectra in 1951 by Dickinson¹ and Gutowsky and co-workers.² Normally in science we expect an exciting new field to draw initially many new participants to it (the 'bandwagon' phenomenon) with a resulting explosion of new discoveries. However, once many of the major questions are answered, ultimately as the field passes from favor (fewer grant funds!), many participants migrate to the next exciting development in science. The vitality of the field is often characterized by a bell-shaped time curve.

The lifetime of a field in science is often disturbingly short, 15 to 25 years. However, this has not been the case with nuclear magnetic resonance, where we find that even after these past five decades we still are on the rising exponential portion of the curve. The reason for the difference of course is that there have been numerous ways of inventing new and exciting applications and understanding of magnetic resonance. As in almost all areas of nuclear magnetic resonance, including ^{31}P NMR, we have seen wave after wave of new scientific disciplines utilizing the rich information provided; with physicists, chemists, biochemists, and medical specialists entering the field. I don't believe that any of the early visionaries of magnetic resonance would have thought that ^{31}P NMR, with such relatively low sensitivity, could ever be used for understanding the detailed structure and dynamics of macromolecules such as DNA. ^{31}P magnetic resonance imaging and spectroscopy now constitute the latest phase of this explosion. Each of these waves has brought ever more diverse and creative scientists into the field.

The development of commercial multinuclear MR spectrometers by 1955, primarily through the efforts of Varian Associates, greatly expanded the application of ^{31}P NMR as an important analytical tool for structure elucidation. By 1956, chemical shifts on several hundred phosphorus compounds had been reported in the literature; the concept of spin-spin coupling which evolved from the pioneering studies of Gutowsky and co-workers on such molecules as PF_3 was also elucidated. Efforts to correlate structure with the theory of chemical shift and coupling constants also evolved from some of these early ^{31}P studies (see leading references in Gorenstein, 1984).³

Early spectrometers generally required neat samples in large nonrotating tubes (8–12 mm o.d.). In the middle 1960s more sensitive, higher field electromagnets, and signal averaging led to further rapid growth in the number of reported ^{31}P spectra and the publication of the first monograph devoted to this field.⁴ With the introduction by 1970 of Fourier transform (FT) and high-field superconducting magnet NMR spectrometers, ^{31}P NMR spectroscopy expanded from the study of small organic and inorganic compounds to biological phosphorus

compounds. Mildred Cohn's original continuous wave ^{31}P NMR spectrum of adenosine triphosphate in 1958 set the stage for the explosion of later biological applications.⁵

In my own laboratory, we began some of the first ^{31}P NMR studies of protein complexes. Our early studies on the binding of mononucleotides to bovine pancreatic ribonuclease A⁶ were attempted in the continuous wave mode on a Bruker HFX-90 spectrometer (90 MHz ^1H). The ^{31}P signal at mM level concentrations of the mononucleotides in the presence of enzyme were often discouragingly buried within the baseline noise. Even CW CAT averaging on a specially constructed data acquisition system was highly irreproducible. With our acquisition around 1970 of a Nicolet 1080 FT data system which we added to our Bruker HFX-90/B-KR 322 S pulsed spectrometer, we could finally reliably see the enzyme complex signal. Early on we realized that instrumentation alone was not our only experimental problem. Variable amounts of trace paramagnetic metal ions often broadened and shifted the signals. Treatment of the samples with a new multivalent metal ion chelating agent (Chelex-100) saved the day. Today of course these are very simple experiments.

Few would have thought that NMR of whole cells could provide any useful high-resolution spectra until the groundbreaking ^{31}P studies of red blood cells by Moon and Richards.⁷ It was soon recognized that these spectra provided information on whole cell metabolism and allowed characterization of heart disease and cancerous tumors.⁸ These ^{31}P studies on isolated tissues and perfused whole organs were followed by localized magnetic resonance spectroscopy and even limited ^{31}P imaging on whole bodies.

With the tremendous increase in sensitivity in modern FT NMR spectrometers, biological and medical applications of ^{31}P NMR spectroscopy grew dramatically during the 1970s, 1980s and continue into the 1990s. A number of monographs^{3, 9–11} entirely devoted to ^{31}P NMR, covering theory and applications to organophosphorus, phosphorus-metal complexes, and biological and medical aspects of the field have been published.

OTHER IMPORTANT ^{31}P MILESTONES

One of the first demonstrations of an ^{18}O isotope shift on a directly bonded nucleus was demonstrated for ^{31}P NMR.^{12, 13} This ^{18}O isotope shift provided a convenient monitor of ^{18}O isotope incorporation into phosphorus compounds undergoing hydrolysis, since integration of the ^{18}O signals relative to the ^{16}O - ^{31}P signal yields directly the percentage ^{18}O incorporation. Separate signals are also observed for each of the multiple ^{18}O -labeled species. Cohn and Hu¹⁴ also showed that a rough linear correlation exists between the magnitude of the ^{18}O isotope ^{31}P shift and the bond order between phosphorus and the isotopically-substituted atom. This dependence on bond order was used in my and John Gerlt's laboratories^{15, 16} to establish the stereochemistry of the ^{18}O label in a prochiral phosphate diester (chiral by virtue of oxygen isotopic differences). This important methodology provided information on the stereochemistry of hydrolysis of a phosphate ester. Indeed, pro-prochiral phosphate monoesters were later synthesized in chiral form by substitution of

the three nonester oxygens by the three stable isotopes of oxygen.¹⁷ This made it feasible to study the stereochemistry of the enzymatic and nonenzymatic hydrolysis of monophosphate esters and anhydrides. In this case use was also made of the quadrupolar broadening of the ³¹P signal by a directly bonded ¹⁷O atom.¹⁸

³¹P NMR has also developed as a powerful probe of the structure and dynamics of nucleic acids in solution. Synthetic methods have now been developed where defined deoxy- (and more recently ribo- and backbone modified) oligonucleotides can be routinely produced in multimilligram quantities. The concomitant development of sequence-specific 2D ¹H/¹H and 2D and 3D ¹H/³¹P NMR assignment methodologies has made the assignment of the ³¹P NMR spectrum of modest size oligonucleotides (8–14 base pairs) possible (see D. G. Gorenstein, *Nucleic Acids: Phosphorus-31 NMR*).

One of the main reasons for assigning ³¹P resonances of oligonucleotides is to obtain information on the conformation of the phosphodiester backbone.^{3,19} The internucleotide linkage is defined by six torsional angles from one phosphate atom to the next along the DNA backbone. Theoretical studies first showed that the conformation of two of the six torsional angles (α : O3'–P–O5'–C5' and ζ : C3'–O3'–P–O5') appear to be most important in determining ³¹P chemical shifts. Molecular dynamics calculations, X-ray diffraction, and 2D NMR spectroscopy have also shown that the phosphate ester conformation is the most variable part of nucleic acid structure.¹⁹ ³¹P chemical shifts and ¹H–³¹P coupling constants have been able to provide valuable information on the conformation and dynamics of the phosphodiester backbone in nucleic acids and protein–nucleic acid complexes.

CONCLUSIONS

³¹P NMR has become an indispensable tool in studying the chemistry and biochemistry of phosphorus compounds. ³¹P magnetic resonance spectroscopy and imaging hold great noninvasive diagnostic promise for the future. Newer NMR instrumentation and experiments have enormously enhanced the application of ³¹P NMR in biology and medicine. It is quite likely that further developments will be seen in the next 50 years.

Govil, Girjesh: Nuclear Magnetic Resonance in India: A Historical Sketch

Girjesh Govil

Tata Institute of Fundamental Research, Bombay, India

Magnetic resonance activities were initiated in a big way in India in the early 1950s by Prof. S. S. Dharmatti, known for his work on the ^1H NMR of ethyl alcohol.¹ He started an active school at the Tata Institute of Fundamental Research (TIFR), Bombay, which was devoted to areas of solid state NMR, high-resolution NMR spectroscopy, and ESR. Some of the early members of Prof. Dharmatti's team were Profs. C. R. Kanekar, Balu Venkataraman, and R. Vijayaraghavan. Almost simultaneously, Saha and Das started an active group at the Saha Institute of Nuclear Physics, Calcutta. Their book 'Theory and Applications of Nuclear Induction' was one of the early texts which covered all facets of NMR spectroscopy.² In the early 1950s, Suryan at the Indian Institute of Science (IISc) pioneered novel experiments on flow studies and sensitivity in NMR experiments.^{3,4} In the initial years, there was an emphasis on the building of indigenous spectrometers and most of the studies were carried out with homebuilt spectrometers. High-resolution experiments were initiated with one of the earliest models built by Varian, a 30 MHz NMR spectrometer.

A number of young people in the late 1950s and early 1960s came back after postgraduate training in western countries and set up NMR centers in India. Special mention should be made of Prof. P. T. Narasimhan who was also responsible for laying the foundations of the Association of Magnetic Resonance Spectroscopists of India. In 1962, the council of the Tata Institute of Fundamental Research decided to appoint Prof. Felix Bloch as an honorary Fellow of the Institute, an honor so far given to only 33 very eminent persons who have helped the growth of this famous institution in India. Prof. Bloch visited India twice and delivered lectures at the TIFR. During this period, NMR became an integral part of chemistry laboratories and chemical industries in India as elsewhere in the world.

Today the culture of NMR has spread all over the country and there are a number of active centers working on various aspects of NMR. However, due to the high cost of present day spectrometers, our efforts may be relatively modest by US standards. Most of the NMR machines are supported by the Government as national or regional facilities and are meant for use by a broad range of academic researchers and industries. There are two major centers which have remained in the forefront of NMR research ever since activity started in India. One is at the TIFR, whose major contributions are in the field of biomolecular NMR, cellular and tissue studies, and in solid state physics. The other is at the Indian Institute of Science, which is known for the development of new pulse techniques and the use of liquid crystals for the determination of molecular

structure. In addition, there are several sophisticated NMR facilities spread over all corners of India, catering to the needs of general NMR users. Recently, good facilities for biomedical research have been set up at the All India Institute of Medical Sciences, New Delhi. NMR has also been applied to agricultural research in India.

India has hosted two major world conferences in the field of NMR. The fifth ISMAR conference was held in Bombay in January 1974. It was during this conference that Prof. Lauterbur announced his results on NMR zeugmatography. Interestingly, this contribution was originally meant to be a short presentation. However, realizing the importance of this area, the organizers decided to give it the status of a plenary presentation. The XIth International Conference on Magnetic Resonance in Biological Systems was held in Goa in 1984. The use of NMR for probing the stereodynamics of biological molecules came into focus during this conference. In addition, a number of schools have been conducted. Prof. Richard Ernst has been the principal speaker at two of these schools.

The international community is generally familiar with the work of Indian scientists. Details of some of the books and monographs published by Indian authors are given in References 5–9.^{5–9}

Post-doctoral work at National Physical Laboratory, Teddington, UK (with Prof. D. H. Whiffen) and National Research Council of Canada, Ottawa (with Dr. H. J. Bernstein). At TIFR 1959–present, currently Senior Professor and Dean; Chairman, ICMRBS, 1993–94; Secretary, Indian National Science Academy (1988–92) and member, IUPAB Council (1990–date). Approx. 170 publications and three books. Research specialties: magnetic resonance in biomolecules and intact cells, and biomolecular electronics.

Grant, David M.: Carbon-13 Magnetic Resonance—An Exquisite NMR Garden of Surprises

David M. Grant

University of Utah, Salt Lake City, UT, USA

*Carbon, carbon quite contrary, how does your garden grow?
With chemical shifts, coupling constants, and spin relaxation
standing in a row.*

INTRODUCTION TO NMR AT THE UNIVERSITY OF ILLINOIS

In 1957 I finished a thesis with Randall Hamm on dimerization kinetics in dioldioxalatochromium(III) complexes and, shortly thereafter, accepted a DuPont Instructorship in Chemistry at the University of Illinois. The freedom to pursue any area of interest led me into NMR which, at the time, was advancing rapidly into the world of chemistry. Illinois was already a premier NMR chemistry center with Herb Gutowsky at the lead and Martin Karplus providing many of the new theoretical foundations in this exciting field. Also contributing extraordinary NMR luster to Illinois was Charles Slichter and his group in physics.

As a graduate student I had been fascinated with quantum chemistry, taught by Henry Eyring, but the simplicity and elegance of spin wavefunctions seemed almost preternatural in their ability to account for every NMR spectral detail and intricacy. It was clear that quantum theory and NMR were harmonious disciplines. Herb and Martin graciously allowed me full access to their research groups, and we soon were involved in both an experimental and a quantum chemical study of geminal couplings in CH_2 groups.¹ Martin also suggested a theoretical analysis of scalar couplings between selected magnetic nuclei and their directly bonded protons.²

Geminal couplings, to be observed, require magnetic nonequivalent hydrogens achievable either with deuterium substitution of one methylene hydrogen or symmetry breaking features such as found in many A_2B_2 coupled systems. The intricacies and deceptively simple spectra that can result in second-order A_2B_2 systems were incompletely appreciated in 1958 even though the A_2X_2 spin system had been discussed in 1955 by McConnell. My first graduate student Charles Hirst finished the A_2B_2 analysis initiated at Illinois.³ Sufficient experimental examples soon existed to confirm our theoretical results on the HCH angular dependence of geminal coupling constants.¹ A gifted associate, Michael Barfield, later described the π -electron hyperconjugative enhancement of geminal couplings along with other structurally dependent features affecting scalar couplings.⁴

The directly bonded couplings of protons with boron and nitrogen by Ogg⁵ and the ^{13}CH couplings in methane and ethylene, provided respectively by Lauterbur and by Muller,

were theoretically analyzed. Bond charge distributions and electron hybridization explained the variations in these directly bonded couplings.² The theoretical work on ^{13}CH couplings initiated for me a lifetime of fascination with the ^{13}C magnetic nuclide and provided the motivation to pursue the resonance of this important but low abundant magnetic nucleus.

The ^{13}C seed had been planted in promising though rocky soil!

CARBON-13 RESONANCE AT THE UNIVERSITY OF UTAH

My daughter, Heidi, born in Illinois, was hospitalized during much of her early life with a serious asthmatic condition due to the midwest climate. This prompted our return west in the fall of 1958 when I was invited to establish an NMR facility at Utah. With our new Varian DP-60 spectrometer, we also obtained Varian's first proton decoupler and dual-frequency probe for observing ^{13}C . The ^{13}C adiabatic rapid passage work of Lauterbur⁶ and an unpublished 1962 continuous wave ^{13}C spectrum by Shoolery provided assurance that naturally occurring ^{13}C resonances could be observed, thereby encouraging Ed Paul with his inordinate persistency, to struggle with the experimental difficulties of this low abundant ^{13}C magnetic spin. Early progress was gradual, but as circumstance would have it the proton decoupler became the crucial component in our first ^{13}C observations in 1960. Significantly, the ^{13}C singlets were enhanced by the collapse of proton splittings, but to our delight an additional increase in intensity was realized also from a proton induced NOE.⁷

*A rather robust ^{13}C seed had sprouted and was growing
steadily!*

With rudimentary ^{13}C spectroscopic tools now in place, a group of very talented graduate students and postdoctoral associates (Terry Alger, Terry Brown, Vern Cheney, Don Dalling, Alan Jones, Bill Litchman, Ronald Pugmire, Werner Woolfenden) worked diligently to establish an early ^{13}C NMR presence at Utah. In these early days the ^{13}C principal investigators (Paul Lauterbur, Endel Lippma, Gary Maciel, Jack Roberts, Jake Stothers, and others) were comparatively few, but they were an inordinately able group and the competition was formidable. These workers are legends in the field and their outstanding accomplishments, upon which our own progress also depended, were crucial to the early development of ^{13}C NMR. Among our promising early results was the striking dependence of ^{13}C shifts upon molecular conformations^{8,9} and upon aromatic properties in benzenoid and nitrogen heterocyclic systems. Many other important structural correlations of ^{13}C chemical shifts, too numerous for discussion in this brief article, also surfaced during the 1960s.

*Carbon-13 seedlings, with both fragrance and nectar, began
beautifying the chemical world!*

NEW CONSTANT FIELD ^{13}C INSTRUMENTS

Jack Roberts, elsewhere in this volume (*Roberts, John D., A Personal NMR Odyssey*), has described his purchase of a digital frequency sweep spectrometer; we followed promptly in 1967 with an analog frequency sweep instrument (Varian

AFS-60) which, with time-averaging capabilities, significantly increased the signal-to-noise ratio due to repetitive ^{13}C spectral acquisitions. As our first constant field instrument, the AFS-60 also greatly simplified the simultaneous double irradiation of both ^{13}C and ^1H nuclei, a condition essential for multiplet collapse and for manifestation of the beneficial NOE. With the AFS-60 Karl Kuhlmann was able to measure quantitatively the proton-induced NOE in ^{13}C labeled formic acid,¹⁰ see Figure 1, in which the maximum threefold ^{13}C NOE was first confirmed. Favorable NOE enhancements had been anticipated over a decade earlier in the seminal work of Solomon.¹¹ Experimental benefits, due to multiplet collapse and NOE, greatly improved both the quantitative measurements and spectral throughput for the less receptive ^{13}C nucleus. We obtained an XL-100 FT spectrometer shortly after its announcement in 1970. This FT instrument, with its improvements in ease of operation and in ^{13}C signal-to-noise ratio, was developed by prominent workers (i.e. Ray Freeman, Howard Hill, Vern Burger among others) at Varian. Fourier transform instruments of this type released the ^{13}C genie from its lamp, and presently routine ^{13}C spectra became available to practicing chemists.

Explosively, the ^{13}C blooms were spreading across the NMR chemical landscape.

Our early research had been governed by the principle, *survey large fields, but cultivate small plots*, and with the significant improvements in ^{13}C spectrometers we focused on some of the exciting smaller ^{13}C plots. Extending Kuhlmann's results, Robin Harris¹² published with us a paper on the

Figure 1 The coupled and decoupled ^{13}C spectra of 23% enriched formic acid exhibit a 2.98 nuclear Overhauser enhancement in peak heights and integrated intensities. The integrals, obtained at slower sweep rates and at expanded sweep widths, were used to measure this factor quantitatively. (Reproduced by permission of The American Chemical Society from Ref. 10)

NOE and its relation to the dipolar spin relaxation.¹³ The prognosis for the future of ^{13}C transient properties was encouraging and during the ensuing two decades a group of outstanding co-workers (Terry Alger, Richard Bertrand, Ed Black, Kenner Christensen, Scott Collins, Don Dalling, Luis Diaz, Paul Fagerness, David Hamill, Ken Ladner, Jim Lyster, Fred Morin, Zu Wen Qiu, Mark Solum, Michele Williams) concentrated on ^{13}C relaxation studies. Various ^{13}C relaxation mechanisms (i.e. ^{13}CH dipole–dipole, scalar coupling, spin rotation, and chemical shift anisotropy, etc.) were delineated and their chemical applications exploited.¹⁴ During my 1972–73 sabbatical leave at the California Institute of Technology, the influence of organic structure and motional dynamics on both ^{13}C and ^{15}N relaxation rates were examined with members of Jack Roberts's excellent research group (Stefan Berger, Fritz Kreissl, Ian Armitage, Donald Giannini, Harry Pearson). Jens Led explained the paramagnetic relaxation of ^{13}C in Mn and Zn amino acid complexes of histidine, work that estimated the distance between unpaired metal electrons and the relaxing carbon nuclei.¹⁵ A consistent dynamical picture began to emerge linking ^{13}C relaxation and molecular motions. For example, the common ^{13}CH dipole–dipole mechanism describes a number of motional features: anisotropic rotation of rigid molecules, internal methyl rotation, methylene pseudorotation, motion of molecules in cavities such as molecular sieves and cyclodextrins, etc.

COUPLED SPIN OR MULTIPLET RELAXATION METHODS

Early in the 1970s it became clear that the proton decoupler used to obtain ^{13}C singlets was obscuring valuable relaxation information contained in proton-induced ^{13}C multiplets. Charles Mayne, a very careful spectroscopist and able mathematical analyst, measured the multiplet relaxation responses of coupled spins in CH_2I_2 with a variety of hard and soft preparation pulses.¹⁶ The multiple exponential character of coupled relaxation, from Mayne's initial work, is obvious in Figure 2. Even the simple $^{13}\text{CH}_2$ moiety requires up to 12 different interlevel transition probabilities to characterize the relaxation processes contributing to multiple exponential responses. This information-rich approach yields spectral power densities for a variety of second-rank (i.e. dipolar, chemical shift anisotropy, etc.) and first-rank (i.e. spin rotation, free electrons, etc.) mechanisms along with cross-correlated relaxation terms between interactions of the same rank and symmetry. An able and energetic group of colleagues (Don Alderman, Jean-Marie Bernassau, Ed Black, Mark Brown, Marie-Therese Chenon, Michael Fuson, Fang Liu, Charles Mayne, Richard Newmark, Wenping Wu, Zhiwen Zheng) provided the experimental foundations and many of the theoretical insights for these advances. In the mid-1970s Larry Werbelow, a premier coupled spin theorist, and an outstanding faculty colleague, Jim Wang,¹⁷ provided a theoretical extravaganza for the group's experimental efforts in multiplet relaxation. The basic formulation of coupled-relaxation principles was largely complete by the late 1970s and summarized accordingly.¹⁸

Extensive data analysis is needed to interpret transient behavior in spectral multiplets as they respond to a variety

Figure 2 Examples of ^{13}C FT NMR spectra of methylene iodide obtained at various times t_0 following the inversion of both proton lines with a hard π pulse. (Reproduced by permission of The American Institute of Physics from Ref. 16.)

of spin polarizations and induced multiple spin orders. Furthermore, these studies are becoming increasingly complex at higher magnetic fields where larger chemical shift anisotropy contributes to the relaxation. Fortunately, the analysis is stable and computer software exists for the simultaneous extraction of many independent relaxation parameters that may be converted with statistical mechanical methods into details on molecular rotation and diffusion and, when present, on the internal motions in flexible molecules.

Since the late 1970s multiplet relaxation studies¹⁹ have focused on applications that extend the tumbling motion of rigid molecules to the internal motions in flexible paraffinic chains such as found in alkanes, in synthetic polymers, and more recently in biological molecules. For example, ^{13}C -labeled methylenes, placed at various positions in nonane²⁰ and in decanol-1, provided a dynamical map of continuous paraffin chains. These data by Mark Brown and Fang Liu on flexible molecules were correlated nicely with theoretical Brownian dynamical models, developed in concert with Glen Evans, Michael Fuson, and Tian-xiang Xiang. Multiplet relaxation methods are being extended and applied presently to amino acids and ^{13}C -labeled peptides by Russ Brown with the anticipation that the differential motional features will eventually provide dynamical maps of important biological molecules. Recent coupled relaxation work by Shi Bei and Craig Taylor in supercritical fluids (SCF) spans the range of densities between gases and liquids and portends high potential for studies in SCF media.

Multiplet relaxation work involves the stimulation of multiple spin orders, similar to those used in multidimensional spectral methods. Thus, these two NMR fields, important to dynamics and structure, have much in common, and the information is complementary. Multidimensional spectral methods produce biomolecular structural maps, while multiplet relaxation methods provide a dynamical map for flexible molecules.

Structural and motional blossoms were becoming increasingly abundant in the ^{13}C garden.

SIMILARITIES BETWEEN ^{13}C AND OTHER LESS RECEPTIVE NUCLEI

The ^2H and ^{15}N nuclides have many of the challenges associated with the ^{13}C nuclide, i.e. all three are low in natural abundance and all have reduced gyromagnetic ratios. These similarities suggested that many ^{13}C methods should be directly portable to ^2H and ^{15}N spectroscopies. For example, the naturally abundant ^2H singlets, obtained by Janet Curtis with proton-decoupling, produce very simple ^2H spectra when compared with the complexity and banding found in many proton spectra. Similar to ^{13}C shifts, these ^2H shifts also have been shown to depend intimately on molecular conformations.²¹ Mary Francis Leopold and Bill Epstein found that variations in naturally occurring $^2\text{H}/^1\text{H}$ isotopic ratios are able to characterize pathways for terpene biosynthesis in plant materials.²² Similar to ^{13}C results, Karen Anderson's ^{15}N shift tensors exhibited a dependence on molecular electronic effects in aromatic nitrogen bases. Her ^{15}N work on solid NH_4NO_3 provides a splendid example of motional averaging of NMR parameters in the solid state.²³

With ^{13}C cultivation methods, hybrids of ^2H and ^{15}N also may adorn the garden of spins!

THE DIRECTLY BONDED ^{13}C – ^{13}C INADEQUATE EXPERIMENT

The INADEQUATE experiment, involving ^{13}C – ^{13}C scalar couplings at the 1% natural abundance level, suffers from the incredibly low signal-to-noise ratio associated with the 1 in 10 000 molecules of two adjacent ^{13}C nuclei. This serious limitation in sensitivity reduces the impact of the INADEQUATE experiment which otherwise has the potential to be the preeminent organic NMR structural method by providing a complete molecular graph of all directly bonded carbon nuclei. Hence, extensive attention has been given to mitigating the low INADEQUATE sensitivity for complex molecules and their mixtures. Reinhardt Dunkel developed a very powerful automatic software routine to recognize INADEQUATE patterns in spectral signals obscured by noise.²⁴ For fairly large molecules, approaching 10 000 daltons, Reinhardt's software provides all of the direct ^{13}C – ^{13}C bond connectivities and the associated scalar coupling constants and chemical shifts. This software also characterizes the line intensities and linewidths. The automated INADEQUATE experiment is especially useful with natural products (e.g. a set of botanical and marine samples collected by Paul Cox, Chris Ireland and their associates were run by Noel Owens, Du Li, Charles Mayne et al.)²⁴ Such automatic pattern recognition methods also portend well for other 2D NMR methods with highly constrained response functions.

Alas, INADEQUATE but delicate ^{13}C flowers sparkle brilliantly under computer magnification!

¹³C CHEMICAL SHIFT TENSORS AND CRYOGENIC TEMPERATURES

Our early interests in ¹³C chemical shifts were revived in an experiment, conducted by Kurt Zilm and assisted by Josef Michl's group, on molecules trapped in a cryogenic matrix.²⁵ Carbon-13 powder patterns from molecules immobilized in nonreactive inert gas media exhibit chemical shift tensors for small molecules that are normally gases at room temperature. The inert gas matrix also approximates closely the environment of molecules isolated in a vacuum, a condition presumed for most quantum chemical calculations. Thus, cryogenic tensor data are especially amenable for theoretical study. A group of key associates (Anita Orendt, Mark Solum, Al Beeler, Henri Strub) expanded on the initial cryogenic work to understand an extensive collection of tensors for small molecules. Our recent emphasis stresses shift tensors for highly reactive intermediates that exist only at cryogenic temperatures. Spectra of ¹³C doubly-labeled molecules in solid argon matrices exhibit the expected ¹³C–¹³C Pake doublets. The splittings depend on the internuclear distances and on the orientation of the C–C bond vector in the principal ¹³C shift axes.²⁶ In reactive or low molecular weight molecules without an easily available single crystal, dipolar spectra often offer the only convenient way to designate the orientation of principal shift axes.

Amazingly, a wild strain in the ¹³C garden flourished even under cryogenic conditions!

CHEMICAL SHIFT TENSORS FROM POWDER SAMPLES AT AMBIENT TEMPERATURES

Tensor data from 1D overlapping powder patterns, whether extracted at cryogenic conditions or ambient temperatures, are limited to simple molecules of only two or three unique ¹³C atoms. While one may resort to ¹³C-labeled molecules of any size to achieve the required spectral simplicity, as done by Arlen Soderquist to observe the three unique α -carbons in phenanthrene, three other avenues have been pursued successfully at Utah to unscramble overlapping spectral bands. These methods include a 1D VAS approach, a 2D orientational correlation method, and a new 2D slow magic angle turning (MAT) experiment. Tensor data from these experiments have been extracted using a POWDER approach²⁷ for frequency fitting and a time fitting approach developed initially by Bill Heeschen.²⁸ Both the POWDER and FID methods are combined with least-square minimization routines to provide accurate tensor spectral parameters.

With a VAS probe, similar to the one designed by Jacques Courtieu²⁹ for controlling the director orientation in nematic liquid crystals, Naresh Sethi³⁰ found that it was possible to scale the width of overlapping tensor bands about their isotropic shifts. Spinning at the magic angle produces a solid state spectrum of ¹³C singlets for each unique resonance. By varying the spinning axis on each side of the magic angle, tensor patterns emerge with widths that depend on the spinning angle. The shape and width of each overlapping band varies about its own isotropic shift, in such a way that a computer is able to extract tensor values for seriously overlapping carbon

resonances providing sufficient spinning angles are analyzed simultaneously.

The 2D orientational correlation approach based on a flipper probe, similar to that of Spiess, has been used by Craig Hughes³¹ and Mao-Lin Hsu to provide the correlated orientational information essential to obtain tensor quantities. By spreading the spectral information in 2D, the resolving power of the experiment is enhanced and very similar principal shift values are more readily identified. This method is especially attractive for polymers and other amorphous solids not amenable for single crystal study and has been used to determine the degree of crystallinity and molecular ordering in polyethylene and related polymers. Recent 2D correlation work on a naphthalene pitch, obtained from the pyrolysis of naphthalene, also indicates promise for the method.

The elegant MAT experiment proposed by Gan³² is generically related to the magic angle hopping experiment of Bax, Szeverenyi, and Maciel.³³ Refined and enhanced by Jian Zhi Hu and others,³⁴ this new MAT method portrays, without detrimental overlap of tensor bands, both the ¹³C isotropic shifts and their tensor powder patterns for relatively large molecules. The method applies a set of repetitive 90° pulses properly spaced with a one-third periodicity over the rotor cycle. Properly processed, the spectrum exhibits both the isotropic shifts and tensor powder patterns along mutually perpendicular directions in a 2D solid state spectrum. Distinct tensors for carbons whose isotropic shifts differ by little more than 1 ppm have been extracted from the two closest vertical slices shown in Figure 3 for two methyl carbons in 1,2,3-trimethoxybenzene. These vertical slices from Figure 3 provide powder patterns of a unique ¹³C tensor without overlap problems. Significant future uses are anticipated for this promising new 2D method because of the wealth of shift information that may be obtained on powder samples.

Novel NMR methods and new applications are bracing as fresh spring flowers!

NMR APPLICATION OF POWDER METHODS IN FOSSIL FUELS

The solid state NMR methods discussed above, including MAS, have been especially powerful in the analysis of structural moieties present in complex fossil fuels. This work with Prof. Ronald Pugmire, a long-time colleague and a close associate from Utah's Chemical Engineering and Fuels Department, has provided innumerable NMR challenges that have their origin in the industrial world. The complexities of applied science, with its attendant economic and societal benefits, often stimulate basic spectroscopic developments of considerable value. Pugmire's unlimited energies and enthusiasm for the latest NMR applications in a number of significant energy-related problems have been assisted by the careful experimental work of outstanding associates (Mark Solum, Larry Alemany, Anita Orendt, Mike Wilson, Yi-Jin Jiang, and others). For example, NMR data characterize the origins and degrees of maturation of various coals. Specific chemical features found in coal include the average size of fused aromatic rings, the chemical nature of bridging groups between the aromatic clusters, and the types of side chains. Such NMR chemical information, with percolation lattice

Figure 3 Fully refocused triple echo MAT spectrum 1,2,3-trimethoxybenzene with the isotropic projection shown at the top. Vertical slices provide high quality tensor powder patterns without serious overlap. (Reproduced by permission of Elsevier Science Publishers B. V. from Ref. 34)

statistics, led to a devolatilization (CPD) submodel critical to our understanding of coal combustion;³⁵ talented co-workers in the CPD development were Ronald Pugmire, Tom Fletcher, Alan Kerstein, Matthew Pugmire, and Mark Solum. While the chemical aspects of coal combustion are much too complex to be explained in every detail by this macroscopic CPD model, the approach works much better than might be expected because the distributed NMR shifts in carbonaceous solids represent faithfully many of the diverse chemical features that affect coal devolatilization.

THE SINGLE CRYSTAL MECHANICAL FLIPPER PROBE

Our interests in chemical shift tensors found their culmination in a new 2D solid state flipper probe designed by

Don Alderman, Carl Carter,³⁶ and Mark Sherwood³⁷ for single crystals. Don, with extraordinary experimental talents and a propensity for novel physical insights, has been an essential member of the Utah ^{13}C laboratory for many years and much of our progress has depended on this able and creative scientist. The single crystal flipper mechanism provides the correlated orientational information critical to the determination of the shift tensor and its orientation in a crystal's unit cell and consequently in the molecular frame. Traditionally, single crystal work required that the crystal be mounted three times in a single axis goniometer and observed by stepping through small angular displacements (about 5°). Unfortunately, less than 20 unique carbon atoms per unit cell can be indexed conveniently in this traditional manner. By flipping between two orientations associated with the time-evolution axes in a 2D spectrum, orientational correlation information may be obtained that addresses ambiguities arising from closely positioned 1D peaks. Figure 4 shows an early example of the 2D single crystal spectrum of 1,2,3-trimethoxybenzene with 36 peaks.³⁸ Note the correlated orientational information and the superior resolution of the 2D spectrum compared with the traditional 1D spectral projections.

Recent single crystal work by Fang Liu and Rob Iuliucci, respectively, has advanced the technique to yield spectra with 56 and 72 resolved peaks. It is estimated that this 2D single crystal method has the potential for indexing considerably more than 100 separate carbon resonances at higher magnetic fields. Single crystal methods determine the principal values of the shift tensor but also give directly the orientation of principal axes in the molecular frame. These experimental data, six numbers for each magnetically unique carbon in a crystal, provide an information-rich representation of the three-dimensional electronic structure of organic molecules. Admittedly, this method requires relatively large single-crystal prisms, a nontrivial indexing of hundreds of tensor values (e.g. 432 tensor values for a 2D spectrum of a unit cell with 72 magnetic nuclei) and a challenging assignment procedure to

Figure 4 Two-dimensional NMR spectrum of a single crystal of 1,2,3-trimethylbenzene showing the resolution of all 36 lines. A rotation of 45° between orientations was utilized. (Reproduced by permission of The Royal Society of Chemistry from Ref. 38)

relate the large number of tensor shifts and their orientations with specific molecular structural features. However, the wealth of electronic and molecular structural information obtained by this approach more than compensates for these efforts.

As with the first fruit of summer, the 2D single crystal results were indeed delectable!

THE THEORETICAL ANALYSIS OF CHEMICAL SHIFT TENSORS

With an increasing availability of experimental shift tensors, it became more important to have good theoretical methods for analyzing the molecular and electronic origins of these tensors.³⁹ Whereas isotropic shifts in liquids have enjoyed great correlative value in designating molecular structure, the six parameters in experimental ¹³C shift tensors provide sufficient new electronic details that the associated molecular features may be specified in much greater depth.⁴⁰ The help of a close and valued associate Julio Facelli and of other theoretical colleagues (Tom Bouman, John Downing, Aage Hansen, Werner Kutzelnigg, Josef Michl, Cu Phung and Michael Schindler) has been essential to our understanding of the experimental shift tensors. We also recognize the use of new GAIO software provided by Peter Pulay, Jim Hinton, and their associates. Theoretical correlation between experiment and theory is now at the point where the calculations are accurate enough to reflect limitations in the diffraction data on which the theoretical wavefunctions depend.⁴¹ Diffraction errors, as they propagate through the wavefunctions into limitations in theoretical shift tensors, are relatively larger than the corresponding experimental shift errors. Thus, it is tempting to look into the future when chemical shift measurements along with improved quantum mechanical treatments of molecular crystals will have the capacity to refine diffraction-based molecular structures.

Theoretical illumination of ¹³C shifts reflects the bounteous harvest of a golden autumn!

Biographical Sketch

David M. Grant b 1931. m. Reva L. Carlow, 1953. B. S., 1954, Ph.D., 1957, Chemistry, University of Utah, USA. DuPont Instructor,

University of Illinois, 1957–58, introduced to NMR by Herb Gutowsky and Martin Karplus. Faculty in Chemistry, University of Utah since 1958, presently Distinguished Professor. Over 300 publications. Awards: 1969 Calif. Section Gold Medal (ACS); 1973 Utah ACS Section Award; 1973–74; Sherman Fairchild Distinguished Scholar, Cal. Inst. Tech.; 1987 Univ. of Utah Rosenblatt Prize; 1991 ACS Award in Petroleum Chem.; 1992 Utah Governor's Medal for Science. Current research specialties: methods and theoretical foundations of carbon-13 NMR, coupled spin relaxation and molecular motions, chemical shifts in liquids and solids with emphasis on carbon-13 shift tensors and their origins in electronic and molecular structure.

Griffin, Robert G.: Perspectives of Magnetic Resonance

Robert G. Griffin

Massachusetts Institute of Technology, Cambridge, MA, USA

EDUCATION

My first contact with NMR occurred fortuitously in my junior year in high school. That year, 1958–59, the Little Rock schools were closed because of the ‘integration crisis’ and I was forced to attend a Pulaski County school, Fuller High School, in Sweet Home, AR. I was fortunate enough to have an excellent chemistry teacher, Dr. Ed Barron, a recent medical school graduate waiting to start an internship, who inspired us in many ways and was constantly suggesting stimulating extra credit projects. One of these, from the *Scientific American* amateur scientist column, turned out to be the construction of an ^1H NMR spectrometer. It was appealing since it involved assembly of a 4.2 MHz radiofrequency oscillator (something that I was familiar with from being an amateur radio operator), a ‘powerful’ 1 kG permanent magnet, and an oscilloscope. The system required a great deal of effort to construct, but in the end my colleague and I detected a signal from a large sample of H_2O .

Following this initial encounter with magnetic resonance, I moved (in both high school and college) into more conventional science of the early 1960s—acid–base equilibria in immiscible solvents and electrochemistry in mixed solvents.^{1,2} However, during my senior year at the University of Arkansas (UA) it seemed clear that, for a person with my interests in physical chemistry and physics, spectroscopy was the natural avenue for the future. This thinking was stimulated further by a molecular spectroscopy course where we discussed a new area, NMR, and what it could tell us about the structure of solids (it was about to replace X-rays as a means to locate protons) and liquids. I found this amusing since I had built one of these instruments as a high school junior. In a chance conversation, the department chair at UA told me that the university where he received his Ph.D.—Washington University (St. Louis) (WU)—had a number of excellent people in magnetic resonance, and suggested that I consider WU for graduate work. I followed his advice without much thought as to other possible graduate schools.

After a semester of courses, I joined the research group of S. I. Weissman. Although Sam was most famous for his research in EPR, he nevertheless had an occasional student performing NMR experiments, and in those years that happened to be me. I was assigned a project to measure the electron transfer rate between the radical ion of trimesitylboron and its diamagnetic precursor by observing the broadening of the ^1H NMR resonances due to exchange. Since the line broadening went as a^2 , where a is the electron nuclear hyperfine coupling constant, I also had to perform EPR experiments to determine a . We succeeded in this endeavor by analyzing a very complicated

EPR spectrum (14 630 lines) via a combination of NMR and EPR.³

As I had been promised, WU had a rich and expanding tradition in NMR and EPR. George Pake spent his early years in St. Louis, and assembled an active faculty in magnetic resonance in the Physics Department. This included Richard Norberg, from whom I took a first course in magnetic resonance, and Maurice Goldman, who had just completed his post-doctoral work as I arrived. The research in physics involved low temperatures, acoustic resonance, EPR of semiconductors, and a topic called magic angle spinning (MAS) on which a student, Horst Kessemier, had just completed a thesis. I remember being told that MAS experiments were possible only because of the abilities of a talented machinist named Otto who could build Kessemier/Norberg rotors. And, as a chemist, I should be interested in these techniques since they had the potential to permit measurement of chemical shifts and J couplings in solids.

Among the seminars I attended as a student, four have remained in my memory. The first was a talk by Raymond Andrew on MAS where I initially saw ^{31}P spectra of PCl_5 and ^{19}F spectra of KAsF_6 illustrating the resolution of chemical shifts and J couplings in solids—as promised by my physics colleagues. He also discussed rotor design (to ~ 10 kHz) and the possibility of using a rotating field rather than a rotating sample. Later Erwin Hahn presented a talk on detection of ‘bundant’ nuclear species with ‘abundant’ spins via destruction of the latters’ signal. This was Erwin’s version of what we now know as cross polarization in solids. In addition, Jake Schaefer visited from Monsanto and presented a theoretical seminar (I had previously met Jake on visits to Monsanto to use their HA-100). Finally, John Waugh spoke at a local ACS symposium on his newly invented multiple pulse line narrowing techniques.

Because of the prior interest in MAS and high-resolution NMR in solids at WU, Waugh’s talk and his papers, which were appearing regularly in *Phys. Rev.* and *J. Chem. Phys.*, stimulated a great deal of excitement. As a result, Sam Weissman recruited a student to work in physics to continue Kessemier’s experiments, and he also went to Holland to see if something called a ‘spiral groove bearing’ could be used for an improved rotor. Everyone was convinced that MAS would be competitive with multiple pulse experiments if only the strength of materials problem associated with high speed rotors could be solved.

Finally, I completed enough electron transfer studies to write a thesis and I began to look for a postdoctoral position. At the time the exciting areas on the horizon were laser light scattering, optically detected magnetic resonance of photoexcited triplets, biological magnetic resonance (which was just beginning to become feasible), and NMR in solids. Following a brief flirtation with laser scattering, I arrived at John Waugh’s laboratory at MIT in May 1970.

POSTDOCTORAL YEARS

Upon my arrival at MIT, Waugh introduced me to his research group which consisted of three postdocs—Michael Mehring, Won-Kyu Rhim, and Dave Ellett—and half a dozen graduate students including Alex Pines, Mike Gibby, Hong-Ning Yeung, and Sam Kaplan. The first problem I encountered in the lab was the overpowering array of homebuilt equipment.

This problem was eventually solved by collaborating with Michael Mehring, who explained pulsed spectrometers to me. Michael is an excellent experimentalist and was responsible for many of the innovations in rf transmitter and probe design of that era. Shortly before I arrived, he had completed an excellent 1 kW amplifier featuring a pair of 4CX250s for the original 54 MHz WAHUA machine. In addition, Pines and Gibby had finished a new high power broad-band pulse spectrometer with the first computerized pulse programmer interfaced to a DEC PDP-12. Thus, we no longer had to hard wire new pulse sequences, but could simply write a new pulse program! The utility of the programmer had just been demonstrated by performing Won-Kyu's complicated magic echo sequences. The WAHUA machine had an elderly Varian iron magnet on it, and the new spectrometer was awaiting delivery of a high field (250 MHz) superconducting magnet from Oxford Instruments. Since the supercon had not arrived, Pines and Rhim had strung cables ~50 ft. down the hall so that they could use the iron magnet and Michael's transmitter at night and on weekends. The problem with this arrangement was that Alex's new computerized pulse programmer would regularly malfunction, causing Mehring's transmitter to emit a continuous 1 kW burst which would destroy the 4CX250s and other selected parts of the transmitter and probe! Ultimately, the superconducting magnet did appear, and, after Dave Ellett and I wrote a machine language FT program for a PDP-8/I (which occupied all 4096 words of 12-bit memory), we separated the spectrometers. Unfortunately, the Oxford magnet never made it much above 100 MHz, but we did not let this impede the science.

After about two weeks of discussion with people in the lab, I settled on a research project for detecting chemical shift anisotropies using MP techniques. We decided to examine ^{19}F spectra because the tensors were supposed to be large (~ 200 ppm). Since motional averaging might be a problem, it seemed important to build a low temperature (LT) probe. I also had to do something about shortening the expected long T_1 values of rigid solids. After a few false starts I doped fluoranil, $\text{C}_6\text{F}_4\text{O}_2$, with a paramagnetic $\text{NO}\cdot$ radical, we repaired a minor dc offset problem in the audio section of the new spectrometer console, and Mehring and I managed to observe the first shift anisotropy powder pattern with a WAHUA experiment.⁴ Subsequently, I built an LT system capable of reaching ~ 10 K and we studied the narrowing of the powder pattern of a CF_3 group from $\eta \approx 1$ to $\eta \approx 0$ due to the threefold hopping with increasing temperature, as well as a number of other ^{19}F shift anisotropies.⁵ This was followed by single crystal studies of ^{19}F shift tensors,^{6,7} and Dave Ellett and I performed a careful examination of ring inversion in C_6F_{12} in the solid.⁸

With the 'original' WAHUA machine, MP NMR was difficult even on good days, and the double resonance experiments that Alex Pines and Mike Gibby were performing were appealing because of their simplicity—cross polarize and decouple. Thus, in the latter part of my postdoc, I became involved in ^{15}N and ^{13}C spectroscopy,⁹ and, in addition, we observed high-resolution ^{14}N – ^{13}C dipolar couplings in single crystals of glycine¹⁰ and acetonitrile.¹¹ I travelled to an ISMAR conference in Israel and to an NMR summer school in Basko Poljé, Yugoslavia where Jean Jeener introduced the world to 2D NMR. There were many exciting discoveries in Waugh's lab during this period—average Hamiltonian theory, magic echoes, shift anisotropies, spin decoupling in solids,

cross polarization, etc—and I felt fortunate to be part of such a stimulating environment.

In 1972 I began to search for permanent employment and eventually accepted a position at the MIT Francis Bitter National Magnet Laboratory (FBNML), where Leo Neuringer, a low temperature physicist, was trying to start an NMR program. Thus, I moved across campus and began to build a spectrometer with the part-time assistance of Dave Ruben, who was finishing his Ph.D. in gas-phase microwave spectroscopy. After completing his Ph.D., Dave spent about three years at Berkeley, prior to returning to MIT. We have remained at the FBNML since that time, and the NMR program has expanded enormously in terms of the number of spectrometers and the number of students and postdocs. The remainder of this paper consists of a description of research at the FBNML since 1972 in a number of different areas.

THE FRANCIS BITTER NATIONAL MAGNET LABORATORY

My first task at the FBNML was to assemble a functioning 'high-field' NMR spectrometer. The end result was a broad-band heterodyne double resonance instrument operating at 300 MHz for ^1H . We built a hardwired pulse programmer capable of performing a few special sequences, power amplifiers delivering 1 kW, and a probe with a goniometer for single crystal studies. Dave Ruben designed the computer interface and wrote the spectrometer software on a PDP-11/20, which we borrowed from the plasma physicists at the FBNML. We have continued the tradition of fabricating much of our own instrumentation since that time—computerized pulse programmers, low level rf components, probes, and a few superconducting magnets. Much of this has been accomplished by Ruben, and more recently, Chris Turner, as well as our long term technicians—Peter Allen, Ajay Thakker, and more recently, Jeff Bryant.

Our first paper was a single crystal study of the $^{13}\text{CO}_2^-$ and $^{13}\text{CO}_2\text{H}$ tensors in an oxalate.¹² At that time 'high-resolution' NMR in solids consisted of creating new schemes for multiple pulse NMR and studies of powders and single crystals. We therefore performed a number of these investigations,¹³ including studies of ^{13}C , ^{31}P , and ^{15}N chemical shifts, ^{13}C – ^{14}N ,¹⁴ ^{13}C – ^{13}C ,¹⁵ and ^1H – ^{14}N ¹⁶ dipole couplings, and ^2H ¹⁷ and ^{14}N ^{18,19} quadrupole couplings and chemical shifts.

LIPID AND MEMBRANE NMR

The 'dynamic structure' of lipid bilayers and membranes has been a topic of continuing interest to the biophysics community for the last 20 years. As we demonstrated with our early study of a CF_3 group,^{5,6} the narrowing of a chemical shift powder pattern with temperature told us a great deal about the dynamics of a molecule, and we thought the same would be true for lipids and membranes. Thus, as our entree to 'biological NMR' we started to examine powder spectra of lipids, first the ^{31}P spectra associated with the head group,^{20,21} then ^{13}C spectra of $^{13}\text{C}=\text{O}$ labeled lipids,²² and finally the ^2H spectra of chain labeled species²³ provided by Sunil Das Gupta. The goal of this work was to elucidate the

structure and dynamic properties of pure and mixed systems. When we initiated this work the standard approach was to employ 'order parameters' to interpret these spectra, as exemplified by the early work of Eric Oldfield and the beautiful experiments of Joachim Seelig with specific ^2H labeling in polymethylene chains. Our goal was different—specifically, to calculate the powder lineshapes based on a reasonable model for the motion. Dick Wittebort produced the first results by successfully simulating the $^{13}\text{C}=\text{O}$ spectra of lipids as they passed through the $L_\beta' \rightarrow L_\alpha$ phase transition.²⁴ These same ideas and Wittebort's computer programs were used by Alfred Blume^{25,26} and Tai-Huang Huang²³ in studies of gel phase lipids and glycolipids, respectively, and most recently in an elucidation of the phase diagram of the cholesterol/phosphatidylcholine system.²⁷ David Rice also used ^2H spectra to characterize the rate of 180° flips of aromatic rings,²⁸ and Kebede Beshah the threefold hopping rate of CD_3 groups.²⁹ Ed Olejniczak, stimulated by the work of Dennis Torchia and Attila Szabo, added T_1 calculations to Wittebort's programs so that the T_1 anisotropy, as well as the ^2H lineshapes, could be used to examine dynamics.³⁰ Barbara Lewis studied mixed lipid systems,³¹ and Carolyn Lee recorded and simulated the spectra of trehalose–lipid mixtures.³²

One of the long-term goals of our research was to calculate the ^{13}C , ^2H , etc. spectra of lipid bilayers in their biologically relevant liquid crystalline phase. Unfortunately, the L_α phase spectra of bilayers exhibit 'fast limit' lineshapes on the ^2H timescale, and therefore the spectra are not sensitive to dynamics. Thus, in order to understand the dynamics, we required a probe sensitive to motion on the 10^8 – 10^{10} s^{-1} regime, and thus the T_1 anisotropy seemed an obvious choice. In two initial searches of pure bilayer systems the expected T_1 anisotropy of ^2H spectra of bilayers was not detected due to an unfortunate choice of the position of the ^2H label; however it had been observed by David Siminovitch and Marty Ruocco in cholesterol-containing systems.³³ Nevertheless, Julia Speyer and Ralph Weber found a large T_1 anisotropy in pure glycolipids and were able to calculate the lineshapes in great detail.³⁴ Thus, the axial diffusion rate and the *gauche*–*trans* isomerization rate at each position of the chain were available from the anisotropy of the spin–lattice relaxation. Interestingly enough, the anisotropy changed sign and was therefore almost zero at the 4 position of the lipid chains where the previous workers had placed their label. In any case, these experiments accomplished a major goal of our research effort. We are continuing our studies of dynamics in solids and membranes.

RETINAL PROTEINS

In the late 1970s Judy Herzfeld initiated our efforts to perform solid state NMR on bacteriorhodopsin (bR), the single protein of the purple membrane of halobacteria, and was enthusiastically advocating MAS experiments for this purpose. MAS as we know it today did not exist, and in addition to isotopically labeling the protein, we had to develop the probes and techniques to perform the spectroscopy. When Gerry Harbison, Judy's biophysics graduate student from Harvard, joined the lab in 1979, he was encouraged to pursue this problem. In 1983 Gerry succeeded in recording spectra of Judy's ^{15}N -lysine labeled bacteriorhodopsin (bR) using

Andrew–Beam rotors in MAS experiments.³⁵ His results showed that the Schiff base linkage was protonated, settling a controversy. More importantly, he demonstrated that MAS NMR could be used to examine large membrane proteins not accessible to solution NMR, and that interesting biophysical information could be gleaned from the spectra. Almost immediately Harbison decided that it would be a great idea to look at the retinal in bR, and did a thorough study of retinals and retinal derivatives as background.³⁶ On a seminar trip to Berkeley I met Rich Mathies, who told me that his colleague Johan Lugtenburg in Leiden had synthesized a large number of ^{13}C -labeled retinals; a collaboration was immediately formed, and Harbison was soon taking spectra of ^{13}C -retinal labeled proteins. Rich, Johan and their colleagues continue to be important collaborators in our retinal protein studies—being involved in essentially all of the experiments. Our first ^{13}C experiments focused on the middle of the chain³⁷ and also on the $\text{C}=\text{N}$ bond conformation,³⁸ which chemical shifts suggest was *syn* and *anti* in bR_{555} and bR_{568} , respectively. In addition, Gerry noted a large downfield shift (~ 10 ppm) in the isotropic shift of the $5\text{-}^{13}\text{C}$ position of retinal, and analysis of the sideband intensities indicated the change resided in the σ_{22} component. We interpreted these results in terms of a perturbed 6-*s-trans* chromophore, the perturbation being due to a 'point charge'.³⁹

The next generation of researchers involved with bR were Huub de Groot and Steve Smith. Huub focused on blue membrane, bR_{605} , and showed that the ^{15}N resonance was shifted farther downfield in this species and developed the idea of a hydrated complex, rather than a single, Schiff base counterion, and a very weak hydrogen bond.^{40,41} Much to our satisfaction, the electron diffraction model of bR, which appeared subsequently, showed a cluster of three residues—Asp-85, -212, and Arg-82 positioned with space for the water around the Schiff base—de Groot's complex counterion. Huub also built a spinning speed controller and developed difference spectroscopy.⁴² Steve did the first work on trapping the M_{412} photointermediate of bR and showed that the retinal was $\text{C}=\text{N}$ *anti* in at least one of the M_{412} s.⁴³ In addition, he and Dan Raleigh began to search for the tyrosinate ion that the optical spectroscopist thought was present in bR and its photointermediates. We looked at $4'\text{-}^{13}\text{C}$ labeled tyrosine where deprotonation has a large effect, and saw a 12 ppm shift with deprotonation in the model compounds. Later Ann McDermott and Margaret Farrar observed no shifts in the protein,^{44,45} suggesting that Tyr was not present. The optical spectroscopy now concurs with this position.

More recently, Ann, Francois Creuzet, Lynmarie Thompson, Michele Auger, and K. V. Lakshmi have been measuring distances in bR and its photointermediates with rotational resonance, confirming some of our interpretations of chemical shifts and extending others.^{46–48} Janet Griffiths, Andrew Bennett, and K. V. Lakshmi have also recently obtained our initial 2D spectra of bR using rf-driven recoupling techniques.⁴⁹ Finally, Jinqia Hu has shown that the 'opsin shift' in bR can be explained by a synergistic coupling of Gerry Harbison's 6-*s-trans* chromophore and the weak complex counterion proposed by Huub de Groot.⁵⁰ Thus, we now believe we understand one of the major problems in retinal proteins—the 'opsin shift'. We are still working on the mechanism of proton translocation in bR and Ling Zheng

has recently demonstrated the possibility of observing proton exchange directly in solids.⁵¹

We have also investigated a number of other large proteins with various MAS experiments. Valerie Copié examined Ala racemase,⁵² thermolysin,⁵³ and Steve Smith examined rhodopsin.⁵⁴ Smith also looked at α -lytic protease⁵⁵ and Ann McDermott and Francois Creuzet studied D-Ala-D-Ala ligase with R² experiments.⁵⁶ Rick Spencer and Michele Auger⁵⁷ initiated a study of β -amyloid in collaboration with Peter Lansbury and Bruce Tidor, currently in progress.

MAS—SINGLE SPINS

Our original motivation for beginning MAS experiments was to obtain high-resolution spectra of model and biological membranes (including bR) without resorting to sonication or detergent solubilization. Because every ‘well-educated NMR spectroscopist’ knew spinning would not work well in the slow spinning regime (at high fields and/or slow spinning speeds), I was not optimistic about the success of these endeavors. Nevertheless, Judy Herzfeld was determined and convinced me to visit Raymond Andrew’s lab during the 1974 AMPERE Congress in Nottingham. I returned with a handful of Andrew–Beam rotors which Judy used as models to design our initial spinners and rotors. Ron Haberkorn completed the probe and recorded the first spectra of lipid bilayers.⁵⁸ In addition, Ron also recorded the spectrum of barium diethyl phosphate (BDEP), illustrating the resolution of a powder pattern into a center band and manifold of sidebands which have appeared in a number of textbooks. These spectra and others led to the Herzfeld–Berger analysis of sideband intensities to extract shift anisotropies. Concurrently, we initiated our efforts to observe spectra of membrane proteins like bR, but progress was slow because of sensitivity and since Andrew–Beam rotors would not spin reliably with wet samples.

Our next MAS project addressed the problem of separation of sidebands due to isotropic/anisotropic chemical shifts. Walter Aue arrived from Ernst’s lab, built a new MAS probe, and recorded 2D spectra of BDEP using synchronous sampling and chemical shift scaling in the isotropic dimension.^{59,60} The scaling ideas were later incorporated into DIPSHIFT experiments (see below), and also combined with TOSS by Dan Raleigh and Ed Olejniczak. In performing scaling experiments Walter quickly encountered ‘rotor lines’ which are due to pulse errors and occur in any MAS multiple pulse experiment.^{60,61} An explanation of these effects based on Floquet theory was later formulated by Olejniczak and Shimon Vega,⁶² who spent his sabbatical at MIT.

During Shimon’s sabbatical we worked on several topics, the most prominent of which was a vector picture of MAS. We developed plots of the magnetization during rotor cycles, and by examining individual and collections of crystallites we were able to demonstrate the formation of rotational echoes.⁶³ In addition, we investigated the effects of π pulses on an echo train and showed the manner in which the echo train could be canceled and recalled. This stimulated a subsequent study of the conditions for echo formation in MAS experiments by Andrew Kolbert and Dan Raleigh.⁶⁴ π Pulses also led to Dixon’s TOSS experiment, and we wrote down a set of equations for the timings of the pulses and proposed a

mechanism to explain how TOSS functions in the case of axially symmetric shift tensors.⁶⁵ TOSS experiments were combined with scaling by Dan Raleigh and Ed Olejniczak⁶⁶ and Andrew Kolbert suggested the TOSSOT experiment (TOSS/reverse TOSS) to separate isotropic and anisotropic chemical shifts.⁶⁷ Finally, Jim Roberts and Shimon Vega collaborated on ¹³C–¹H shift correlation experiments.⁶⁸

MAS—RECOUPLING EXPERIMENTS

In the closing days of my postdoctoral appointment in John Waugh’s lab, Alex Pines and I recorded ¹³C single spectra of glycine and observed ¹⁴N dipolar couplings.¹⁰ Although I had come to Waugh’s lab imbued with the idea of suppressing dipolar interactions in solids, I began to wonder if it were possible to (in the words of Mike Munowitz) ‘reintroduce these couplings in a manner consistent with the goal of high resolution’ — to perform high-resolution dipolar recoupling experiments. Ruth Stark and Ron Haberkorn did several experiments on ¹³C–¹⁴N, ¹³C–¹³C, and ¹H–¹⁴N dipole spin pairs in single crystals,¹³ but we clearly needed a more generally applicable approach to perform structural studies in solids.

In 1979 a ‘separated local field’ experiment for static solids was reported, and shortly thereafter I was reading a reprint by Waugh on MAS and realized it should be possible to combine the SLF idea with spinning. Specifically, since the heteronuclear coupling is inhomogeneous, we should obtain dipolar sidebands from which we could measure heteronuclear distances. I discussed this with Geoffrey Bodenhausen, who was at the FBNML at that time, and we decided that it would be important to synchronize the experiments with the rotor, since there would otherwise be phase distortions of the sidebands (we now appreciate this problem can be corrected with a shearing transformation⁶⁹). Thus, we arrived at a scheme which included Geoffrey’s favorite refocusing pulse at $n\tau_r$ with sampling initiating at $2n\tau_r$, a pulse sequence identical to that which Geoffrey and Ruth Stark had used in ¹H–¹⁴N single crystal studies.¹⁹ WAHUA was used to remove homonuclear dipole couplings during t_1 leaving only heteronuclear couplings, and the t_2 dimension had only the chemical shift. We referred to this experiment as the dipolar/chemical shift (DIPSHIFT) experiment. Initially Mike Munowitz, Chris Dobson’s ‘solid state student’ from Harvard, tried this experiment on Ca(CHO₂)₂⁷⁰ using a new spinning probe constructed by Tai-Huang Huang. It functions well for strong couplings found in ¹H–X systems, and Mike analyzed the dipolar sideband patterns for several versions of DIPSHIFT in great detail for his thesis.^{71–73} Versions of DIPSHIFT have been employed by Jake Schaefer to study dynamics and by Stan Opella to measure bond distances in DNA. DIPSHIFT was the first successful *dipolar recoupling* experiment in MAS.

It was clear that molecular structure determinations would require that weak dipolar couplings—between ¹³C–¹⁴N, ¹³C–¹³C, and ¹³C–³¹P—would have to be measured. Andrew Kolbert attempted to employ pulse trains to enhance sideband amplitudes in DIPSHIFT experiments⁷⁴ and while these schemes were successful they were only applicable to directly bonded systems. What was needed were techniques applicable to weak couplings not arising between directly bonded spin pairs.

At the time there was a double ^{13}C labeled glycine sample around the laboratory, left over from measurements of double quantum spectra in solids.⁷⁵ Dan Raleigh performed a MAS experiment with this sample and happened to observe a pronounced broadening of the ^{13}C resonances at a spinning speed equal to one-third of the isotropic shift difference. We had rediscovered rotational resonance (R^2), a phenomenon initially reported by Raymond Andrew in 1963/65. We described the broadening in glycine and other spectra in a short paper and pointed out that this was a recoupling effect which could provide internuclear distances.⁷⁶ For long distances or weak couplings the lineshape effects were too small to be useful, so I proposed a magnetization exchange experiment at R^2 for such cases to Dan and Malcolm Levitt. Malcolm remarked that the magnetization would oscillate between the spins, Dan confirmed this result on ZnAc, and Malcolm wrote the first program to simulate the exchange.^{77,78} Francois Creuzet had just arrived in the lab and built a new high-speed spinning probe which he and Dan used to explore experimentally a number of R^2 phenomena and showed that they could measure distances up to $\sim 5 \text{ \AA}$ in TEE.⁷⁹ Subsequently, Francois and Ann McDermott performed the first R^2 distance measurements on a protein.^{56,80} We and others are continuing to explore R^2 and apply it to different systems—for instance the β -amyloid protein. R^2 phenomena have been studied by Beat Meier in Richard Ernst's lab, by Zhou Gan in David Grant's lab, and by Charles McDowell and co-workers. Shimon Vega and Asher Schmidt wrote a theoretical description based on Floquet theory.

The problem with R^2 (and REDOR in its present form) is that it measures one distance at a time. Thus, it is difficult to accumulate enough data to determine a structure quickly. Broadband multidimensional experiments (which we refer to as rf driven recoupling) addressing this problem were initially considered in our lab by Jong Ok and most recently by Andrew Bennett⁸¹ and Dan Sodickson⁸² along with Levitt and Vega. The experiments consist of longitudinal mixing schemes with one π pulse per rotor period to perform the recoupling. At the latest ENC there were about a dozen papers on this topic, so it is an area of active research. One of these was by Boqin Sun and Phil Costa and relies on rotor synchronized spin locking fields to produce a DRAMA-like Hamiltonian for recoupling in an experiment which we call MELODRAMA. It is also amusing to witness the full circle that this area of NMR has executed. In 1948 George Pake told us that NMR could measure distances in solids by examining dilute spin pairs, but in the 1950s and 1960s we discovered that spin pairs were not too common via broadband solid state NMR spectra. In the 1970s, thanks to John Waugh, we recovered the chemical shift, and now in the 1990s we are routinely reintroducing dipolar couplings among pairs of spins in high-resolution spectra.

HIGH FIELD DNP AND EPR

In 1985 David Singel arrived at Harvard University and we began to discuss a number of problems in magnetic resonance. We had been performing MAS experiments at the FBNML for what seemed like an eternity and I was looking for a new and completely different research topic. In addition, we had developed a number of dipolar recoupling experiments in the lab, and we were constantly faced with the realization that

these experiments would benefit enormously from an increase in the signal-to-noise ratio. David had just completed a postdoc at IBM with Nino Yannoni and had assembled a spectrometer for dynamic nuclear polarization (DNP) NMR. A few years earlier Dan Raleigh and I, stimulated by Robert Wind's 40 GHz DNP experiments, had talked extensively about the possibility of using DNP to enhance signals in MAS spectra. We came to the realization that suitable high-frequency, high-power microwave sources were the major stumbling block to DNP experiments at higher fields. Rick Temkin, a colleague in the MIT Plasma Fusion Center, suggested the answer to our problems was a gyrotron, a high-power, high-frequency microwave source which employs a superconducting magnet, rather than a slow wave structure, to generate the microwaves. As a result David, Rick and I submitted for an NIH grant to build a 140 GHz (2 mm) gyrotron and a 210 MHz DNP/NMR spectrometer to go with it. The grant was funded and we began construction in 1987.

In recent years, DNP experiments by Robert Wind, Nino Yannoni, and Jake Schaefer and Ed Stejskal have been performed at 40 GHz but the EPR spectrum was not examined. However, we suggested it was also important to perform high field EPR, since the EPR spectra would change dramatically with a factor of 15 increase in field strength, and we would need to know where in the spectrum we were irradiating. Thus, Ralph Weber joined us from Leiden and began ordering parts for the EPR. He was succeeded by Thomas Prisner who, together with Sun Un and Ann McDermott, performed our initial CW and pulsed EPR experiments. Ann started to assemble the NMR and Sun Un initially was in charge of the gyrotron. Ken Fishbein and Brenden Bellew were the two students involved in the spectrometer construction.

The 140 GHz EPR worked first. We therefore recorded spectra of several model test systems and photosystem-I, and we did pulsed EPR experiments with a pulsed EIO borrowed from PFC.^{83,84} Slightly later we finished the NMR and used the pulsed EIO for our initial DNP experiments in which we saw enhancements of ~ 10 .⁸⁵

After much work, Lino Becerra finally brought the gyrotron into operation and we obtained our initial DNP results with it as the microwave source.⁸⁶ Gary Gerfen, Brenden Bellew, and our technician Jeff Bryant have improved the EPR immensely with cylindrical resonators which we are also using for DNP. High field EPR spectra of paramagnetic proteins, contrary to the expected wisdom, are thus far very impressive.⁸⁷ Late in 1993 we obtained our first 140 GHz microwave switches and have performed pulsed EPR and some more pulsed DNP experiments. Recently we have achieved enhancements of 185 in a water/glycerol/TEMPO mixture and transferred this polarization to the carbon-13s in a solute, glycine.⁸⁸ These enhancements translate to reductions in signal averaging times of $>10^4$ or reductions in sample size of $>10^2$. We are still improving the instrumentation, and new scientific problems appear regularly.

THE FUTURE

Most of the research topics mentioned above are still under investigation by the current group of students and postdocs in the laboratory. Joanna Long, John Gross, and Sunil Das Gupta are probing the dynamics of lipid bilayers and seeking new

methods for performing spectroscopy. Joanna, Doug Maus, Jinqia Hu, Boqin Sun, Janet Griffiths, and Ani Petkova are working on bR and retinal proteins. Phil Costa and Janet are working on the structures and spectroscopy of peptides and amyloid proteins. Boqin, Phil, and Andrew Bennett are heavily involved in new MAS methodology. Dennis Hall, Brenden Bellew, Souhiel Inati, Gary Gerfen, and Lino Becerra are performing high-frequency DNP and EPR experiments. Three new students—Chad Rienstra, Henry Spindler, and David Rovnyak—recently joined the group and have yet to select thesis topics. With this group of individuals and research topics, the future will be as exciting as the past.

Biographical Sketch

Robert G. Griffin. b 1942. B. S., 1964, University of Arkansas, Ph.D., 1969, Washington University (St. Louis), Post-doctoral Fellow, Dept. of Chemistry, MIT 1969–72; staff member Francis Bitter National Magnet Laboratory, MIT, 1972–1989; Professor of Chemistry, MIT, 1989–current; Director, Francis Bitter National Magnet Laboratory, 1992–current. Approximately 210 publications. Research interests include development of new methods for performing high-resolution NMR experiments in solids, high-frequency DNP and EPR, and applications of these techniques to problems in biological, chemical, and physical systems.

Günther, Harald: From Organic Chemistry to NMR—A Personal Experience of Magnetization Transfer

Harald Günther

University of Siegen, Germany

My first encounter with NMR was in the late 1950s while I was still a graduate student of chemistry at the University of Heidelberg, during a visit to the AICHEM, the international exhibition of chemical instrumentation at Frankfurt, where a presentation of the Swiss manufacturer Trüb & Täuber displayed a formidable instrument. I still remember the dark red color of the cabins with the electronic parts, exclusively valves at that time, and a friend, several years older than myself, told me that in his department somebody had just delivered a seminar about a new technique dealing with nuclear magnetism. This episode had no immediate consequences. However, as my Doktorvater, Georg Wittig, several years later, when I was about finishing my Ph.D. work in his laboratory, suggested I should take up a postdoctoral position at the Mellon Institute with Aksel A. Bothner-By in order to get acquainted with a new physical method for the investigation of chemical structures, known as nuclear magnetic resonance; a decision was taken which has determined my further career and indeed my whole life.

When I came to Pittsburgh in 1961, the Mellon Institute had just received the first Varian A-60 NMR spectrometer and Barry Shapiro was in charge of this instrument. I joined Aksel's research group which was working at that time on rotational isomerism in olefins. My immediate duty was to synthesize a number of substituted propenes and only later was I initiated into the secrets of operating the A-60 and introduced to the analysis of ^1H NMR spectra. In addition to the private seminars in Aksel Bothner-By's office, where Barry Shapiro and I sat on one of those low leather sofas while Aksel explained energy level diagrams at the board, the books by John D. Roberts on applications of NMR to organic chemistry¹ and on spin–spin coupling² as well as Jackman's monograph³ guided the beginner, who now and then had the courage to look into Pople, Schneider, and Bernstein.⁴

The art of NMR spectral analysis started to develop at that time and the Pittsburgh group had established the program *FREQINT IV*, which allowed the calculation of stick spectra from trial parameters. No iterative process was available and the analysis proceeded by visual comparison of the calculated and observed spectra. From the observed differences one had to derive changes in the initial parameters which, hopefully, would improve the fit. In most cases they did not. Computer time was available for our group at a private computer center in downtown Pittsburgh and an afternoon on the IBM 704 high-speed computer was easily invested in a number of trial and error attempts with the spectrum of 3-chloropropene (1)

and those of related compounds.⁵ This was the first time I learned that research also costs money. Real progress was then made after an iterative procedure for parameter improvements was added to the program which from then on was called *LAOCOON*. The final version emerged after Salvatore (Turi) Castellano joined the group in 1962 and became available later as the famous *LAOCOON II* package.⁶

At that time quite a number of substituent effects were unknown in proton NMR spectra and with Turi we worked on a project which originated from an unexpected chemical shift effect. Vinicio Mini, an Italian postdoc working with W. Grundmann in the field of heterocyclic chemistry, had synthesized methyldiphenyl-*s*-triazine (2) and the ^1H NMR spectrum of this compound was routinely measured with the A-60. With this instrument the spectrum was usually scanned in the ^1H chemical shift range of 0–8 ppm, and low-field regions were investigated only in rare cases. To his surprise, Mini missed two proton resonances of the phenyl rings which were later found—quite unexpectedly for such a structure—at fairly low field. Several mechanisms were recognized consequently as the origin of this unusual deshielding for phenyl protons.⁷

While our work was thus completely confined to proton NMR with perhaps a ^{19}F spectrum now and then, in another laboratory at the institute, Paul Lauterbur was trying hard to find ^{13}C signals in natural abundance, an esoteric enterprise at that time.⁸ As I heard later, one day he was visited by the FBI. With his 8.5 MHz transmitter he had hit the local FBI frequency network and they located the uninvited participant. Across from my lab, Harold Conroy, originally a natural products chemist at Yale and one of the fathers of the Karplus–Conroy curve,⁹ worked on the exact solution of the Schrödinger equation. Organic research fellows like Satoru Masamune or Eugene LeGoff provided interesting compounds for NMR studies.

Back in Germany, my original plans to start research in the field of mechanistic organic chemistry at Heidelberg changed. Emanuel Vogel at Cologne University invited me to join his institute as assistant in charge of the newly acquired A-60. This turned out to be a unique opportunity to continue with NMR and, together with Detlef Wendisch as my first Ph.D student (now an NMR spectroscopist with Bayer AG at Leverkusen), we investigated rotational isomerism in vinylcyclopropanes (3).¹⁰ Analysis of the ^1H NMR spectra of these systems required extensive calculations and we were relieved when Aksel Bothner-By on a visit to Cologne in 1964 provided us with the final version of the *LAOCN III* program. At that time the University of Cologne had no computer center and our spin analyses were run at the nearby University of Bonn which was in possession of an IBM 7090 computer. So, several afternoons in the week we went to Bonn by train and came back in the evening with the r.m.s. error reduced by a few millihertz. Nevertheless, the work eventually established the three-well potential for internal rotation in vinylcyclopropane.

Apart from this project, my interest was caught by the compounds coming from Vogel's group. In October 1963, shortly after I arrived at Cologne, they succeeded in preparing 1,6-methano[10]annulene (**4**), which proved to be the start to a chapter of fascinating syntheses of bridged annulenes.¹¹ These systems were, of course, nicely tailored for spectral analysis with the A-60 and apart from ring current effects, which were exciting chemists in the 1960s, gave interesting relationships between bond properties and proton spin-spin coupling constants.¹² During my time at Mellon I had already had a brief glimpse of this field as Lloyd Jackman gave a seminar where he reported the peculiar NMR behavior of Sondheimer's [18]annulene.¹³

One of the most exciting molecules at that time was oxepine, synthesized in Vogel's group for the first time. Walter Böll, who was engaged in the successful synthesis of oxepine, first noted the strong solvent dependence of the UV spectrum of this compound and my ¹H NMR work revealed peculiar chemical shifts for the α -protons and a strong temperature and solvent dependence of these resonances.¹⁴ Clearly, an oxepine-benzene oxide equilibrium (**5** $\rightleftharpoons$ **6**) was indicated; however, the respect for the aromatic character of benzene was so strong among organic chemists that it was difficult for them to believe that benzene oxide should be a stable compound. Obviously, low-temperature NMR measurements were necessary to settle the question and since the A-60 available at Cologne was limited to measurements down to -60°C , I had to go to Freiburg where Horst Friebolin, who was in charge of the NMR equipment at the Fraunhofer-Institut headed by R. Mecke, had offered me the opportunity to run some low-temperature spectra. So, one day I took the Loreley express, one of the fast trains going south, a Dewar filled with dry ice containing the NMR tube with oxepine prepared by Walter Böll in my bag and went to Freiburg. What followed was an exciting afternoon and evening at Friebolin's DP-60 spectrometer and when much later I returned to my hotel, I spent a few hours more looking at the spectra where we had recorded the line broadening at low temperature and which finally showed the splitting into two separate signal sets for the two isomers¹⁵—a truly memorable and exciting moment. In this context it should be mentioned that the whole field of degenerate valence isomerizations could not have been developed without NMR, and the pioneering work of Doering and Roth¹⁶ on homotropyliene and Schröder¹⁷ as well as Saunders¹⁸ on bullvalene are true landmarks in this field.

While working on oxepine, I frequently visited Freiburg which was an active NMR center at that time. In addition to Friebolin's work on conformational analysis,¹⁹ Dischler and Englert had developed direct methods for the analysis of AA'BB' systems²⁰ and Saupe and Englert had discovered

the alignment of small molecules in liquid crystals.²¹ While visiting Alfred Saupe one day, he showed me his beautiful 50-line spectrum of benzene dissolved in a mixture of liquid crystals.²²

As time went on, the NMR frequencies increased and we acquired a Varian HA-100 at Cologne. This improved our low-temperature work, gave the basis for real double resonance experiments, and for the first time allowed us to study small molecules oriented in liquid crystals.²³ Being an optimist, I had also ordered a probe for ¹³C NMR which was, however, never used. It was only after the invention of the Fourier transform technique that we entered this field and my first spectra were run in 1970 during the evenings at an NMR workshop organized by Robert Kosfeld at Aachen. After finishing my seminars on proton NMR and chemical structure, I ran down to the basement of the institute where Toni Keller of Bruker was operating the first 15 MHz ¹³C FT NMR spectrometer. During the meeting we finished a project on norcaradiene-cycloheptatriene isomerism, (**7**) and (**8**), which lent itself to ¹³C analysis because of the large chemical shift difference existing between the 1,6-carbons in both structures.²⁴ My complete ignorance of computer techniques led to an error in the chemical shifts we recorded, because instead of using multiples of 2¹⁰, I converted the digitized data for the line positions by decimal numbers which gave an error of several ppm for the high frequencies. However, I shortly became acquainted with ¹³C FT NMR as we purchased at Cologne a Bruker HX-90 spectrometer equipped with a Nicolet 1080 computer. On starting to measure proton decoupled ¹³C spectra, the quantum mechanical know-how about spin analysis soon faded away in my group and after a few months my students completely ignored the HA-100.

Working in an institute for organic chemistry, my contact with NMR groups was confined exclusively to workshops and international meetings. The 13th Colloque AMPERE at Leuven 1964 was the first conference I attended and I still remember an impressive lecture by Solomon. At the 8th European Congress on Molecular Spectroscopy which took place in 1965 at Copenhagen, a larger number of high-resolution NMR contributions were presented. To my own surprise I was asked to chair one of the sessions, with the most famous speaker during the afternoon being Ray Freeman.²⁵ A red lamp had been installed on the front table in the lecture hall in order to remind the speakers of the time-table which was quite naturally rather crowded because posters had not yet been invented. When Freeman's time ran out, he gave no indication that he would come to an end. I was probably convinced that everybody should be treated alike and after a few minutes I pushed the button. Freeman was not at all impressed. Instead he took a box which was on the table, put it over the lamp and continued. The loud peal of laughter from the audience showed me that I certainly did not know enough about this speaker.

In Germany, meetings on NMR which dealt with applications in chemistry only became a regular practice after an NMR

Discussion Group was founded in 1974. The initiative for this came from Ernest Lustig who had returned to Germany shortly before. The first meeting was organized in Frankfurt by Horst Kessler, and during our fifth meeting, arranged by the late Gerhard Binsch in 1978 at Kloster Ettal south of Munich, the NMR Group applied for membership in the Society of German Chemists (GDCh). Since then, regular meetings have been held every year and the group has now, after German reunification, more than 400 members.

In 1977 I moved from Cologne to Siegen, one of the newly founded universities in the state of Nordrhein-Westfalen. This provided the basis for acquiring a high-field spectrometer, and in May 1979 we charged our 400 MHz superconducting magnet. The world of NMR would soon become even more exciting as the newly developed two-dimensional techniques entered the laboratories and multinuclear experiments became routine. In addition the enormous breadth of NMR nowadays, which has gone far beyond the borders of physics and chemistry, and its fascinating applications in chemistry make it still one of the most attractive areas in modern science.

Gutowsky, Herbert S.: The Coupling of Chemical and Nuclear Magnetic Phenomena

Herbert S. Gutowsky

University of Illinois, Urbana, IL, USA

INTRODUCTION

If nuclear magnetic resonance had not been discovered by Purcell¹ and Bloch,² chemists would have had to invent it, because without NMR the world's understanding and use of chemistry today would not be nearly as profound or as extensive as it has become. Some evidence of this is given in Figure 1, taken from a review article that Jiri Jonas and I published in 1980.³ It shows the number of scientific articles per year with NMR key words in *Chemical Abstracts* over the 1970s. Since then the number has continued to grow and is now approaching 10 000 per year.

This remarkable utility of NMR has two main sources. First, NMR observables are affected by a wide range of interactions between magnetic nuclei and their chemical surroundings, i.e. within a few Å. Second, our technology, principally ultra-high-resolution superconducting solenoids and computers, makes it feasible to observe even very small chemical/nuclear interactions on microgram samples. I had the rare good fortune to be the first chemist to explore the synergistic coupling of chemical and NMR phenomena. This is an account⁴ of some of my early experiences and impressions along the way.

In their initial NMR experiments, the physicists were not seeking a novel way to study chemistry. They were motivated mainly by interest in a simpler method for determining nuclear moments and spins. At that time the methods of choice used very difficult atomic and molecular beam techniques. The first attempts to detect nuclear magnetism in bulk samples were

those of C. J. Gorter in the Kamerlingh Onnes Laboratory at Leiden in 1936 and again in 1942.^{5,6} They were unsuccessful, probably because of a poor choice in the chemical state of the samples.

Gorter used KF or LiCl powder in the tank coil of an rf oscillator. The sample was kept at low temperatures to improve the Boltzmann factor and signal strength, and the static magnetic field was swept slowly through the probable resonance regions for F and Li. The 1936 experiments⁵ attempted to detect a rise in temperature of the sample at the resonance condition and the 1942 experiments⁶ looked for a change in inductance of the coil and in oscillator frequency. We now know that the desired effects were weakened by the large dipolar broadening of the resonance in solids, by saturation due to the long spin–lattice relaxation time (T_1) in solids at low temperatures, and by inhomogeneity broadening from the applied magnetic field.

Why were Purcell and Bloch successful in detecting magnetic resonance and Gorter not? From conversations with them I learned it wasn't because they knew any better what they were doing, but because they tried the right things for the wrong reasons. Both sought to detect the resonant absorption of radiofrequency energy by magnetic nuclei at ambient temperature. Purcell wanted a high concentration of strongly magnetic nuclei. He had become familiar with paraffin wax as a proton-rich neutron shield in cyclotron research during World War II. So he chose 850 cm³ of the 'solid' wax¹ as his sample. The unconsidered high molecular mobility in the wax at room temperature gave a strong, somewhat motionally narrowed proton resonance with a shortened T_1 and was relatively easy for them to detect.

Bloch wanted to avoid samples with a long T_1 which would saturate too readily and thereby give a weak signal. So he used a water sample doped with paramagnetic ions to shorten T_1 and also looked for the proton resonance. Here too the molecular mobility of liquid water led to a narrow, strong signal which was readily detected.² In both instances the key to success was the narrowness and shortened T_1 of the resonance due to the motional averaging of the dipole–dipole interactions.

DIPOLAR BROADENING AND MOTIONAL NARROWING AT HARVARD

The way I became aware of NMR and started research on it has some anomalous aspects. While Purcell and Bloch were making their discoveries at MIT and Stanford in late 1945, I was a graduate student at Berkeley finishing a master's degree in chemistry with Ken Pitzer. The quickest way for me to get into NMR would have been to go across the Bay Bridge from Berkeley to Stanford and work with Bloch. Instead, in February 1946, I went to Harvard where in the fall of 1947 I ended up working with Purcell and George Pake as a student of George Kistiakowsky.

In practice, my introduction to NMR resulted from an unlikely chain of events. My M.S. thesis work with Pitzer was on the electron-deficient dimers formed by Group III compounds such as the aluminum alkyls and borane as illustrated in Figure 2. At that time the nature of the bonding responsible for the dimerization was highly speculative. Two

Figure 1 NMR articles per year contained in *Chemical Abstracts* for the period 1967–78³

Figure 2 Group III electron-deficient molecules that dimerize

Figure 3 Ethylene-bridge and ethane-like structures proposed for diborane

structural models were in vogue and it was a matter of choosing between them. In the classical case of diborane, the two structures are the ethylene-bridge and ethane-like types shown in Figure 3. My cryoscopic study of the dimerization of the aluminum alkyls did not shed much light on the nature of the bonding. It encouraged me, however, to give a group seminar on diborane at Harvard and perform a couple of unsuccessful experiments on its chemistry.

My initial Ph.D. research problem with Kistiakowsky at Harvard was to obtain an infrared spectrum of the methyl radical as a means of learning something about its structure. It was a significant problem but technically very difficult. It proved to be beyond me and in fact wasn't completed successfully until 15 years later, by someone else with new technology. So I found myself knowing how to run E. Bright Wilson's homemade infrared spectrometer⁷ and having on hand a supply of dimethylmercury which I'd prepared as a source of methyl radicals. I hated to see the effort I'd put in on the problem be entirely wasted, so I checked the literature and found that the vibrational spectrum had not been reported for dimethylmercury. This led me to run the Raman as well as the infrared spectrum of the compound, and do a frequency assignment and normal coordinate analysis of the results. Later I did the same for the zinc and cadmium homologs.

By the middle of 1947, I had completed most of these tasks, admittedly of a fairly pedestrian nature. However, Kistiakowsky wasn't about to grant me a Ph.D. from Harvard on the basis of the infrared and Raman studies alone. So we cast about for something else to keep me busy. At this point serendipity entered in a major way. One day in early September Kisty had lunch with Ed Purcell at the Harvard faculty club, where Purcell told him about the NMR technique which a graduate student of his, namely George Pake, was using to determine the proton-proton distance in the water molecules of solid gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$.⁸ The proton lineshape of a powder sample is shown in Figure 4.

The only magnetic nuclei in the sample are the protons which occur in close pairs. The strong, magnetic dipole-dipole interactions in the pairs lead to the very broad Pake doublet pattern in the figure, at the bottom of which is the first derivative observed for the NMR absorption while the top gives the integrated lineshape. The dependence upon the inverse cube of the interproton distance of what is now called

Figure 4 The broad proton lineshape of powdered gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$. The first derivative is at the bottom and the integrated lineshape at the top⁸

the Pake splitting led Kisty to suggest that the proton NMR spectrum of diborane might differentiate between the ethylene-bridge and ethane-like structures. The two protons in the bridge should be closer than the two protons in the terminal BH_2 groups, whereas in the ethane-like structure the three protons at each end would have the same separation. In turn, one might expect a large and a small dipolar splitting for the ethylene-bridge structure and only one splitting for the ethane-like structure.

So, on September 19, 1947, after an enthusiastic conference with Kistiakowsky and a meeting between myself and George Pake, I began my initiation into NMR. My initial tasks in the collaborative exercise were those appropriate to a chemist. I was to synthesize the compound. My other task was to build some sort of cryostat which would freeze the sample so that the proton-proton dipolar interactions weren't narrowed by the molecular mobility in the liquid. This job was complicated by the fact that the permanent magnet being used by Pake had only a 0.75 in. gap. The result was not a thing of beauty nor a technological triumph, but it worked. The sample was placed in a 0.375 in. o.d. Pyrex tube and inserted into a hollowed-out copper block which conducted heat into an insulated brass can containing liquid nitrogen.⁹ The main problem with the cryostat was the high rate at which it consumed liquid nitrogen, then relatively expensive and hard to get, which Kisty provided. The rate of consumption was about 5 L h^{-1} and for years afterward, whenever I visited Harvard, he would remind me of the large amount of liquid nitrogen George Pake and I boiled off in the experiments.

On February 21, 1948, Pake and I made our first low-temperature run on the proton resonance of diborane. This was done with an rf bridge system, using 30 cycle modulation

Figure 5 Derivatives of the proton magnetic resonance lines observed at 29.0 MHz in polycrystalline ethane, disilane, ethylene, and diborane at 90–95 K⁹

of the magnetic field with a lock-in detector.⁸ The main field of the permanent magnet was swept manually via a rheostat which adjusted the dc current through a set of biasing coils, and the first derivative of the absorption was recorded by watching an output meter and writing down its value on a point-by-point basis. George did the field sweeping while I monitored the liquid nitrogen and the temperature and did the writing. What we hoped to see was the derivative of an absorption line bearing some resemblance to that of the proton doublet found by Pake for the water of crystallization in powdered gypsum.

What we actually observed bore little resemblance to this; the results are shown at the bottom of Figure 5. It is the derivative of a broad line, featureless except for a small spike in the center. My disappointment at seeing nothing resembling a doublet structure was compounded by confusion about the origin of the sharp spike at the line's center. The melting point of diborane is only 108 K, so for some time we thought that

part of the sample might still be liquid because of the crudity of the cryostat which gave a sample temperature of 90–95 K. However, after spending several days transferring the sample to a larger tube and otherwise improving its thermal contact with the liquid nitrogen, it became apparent that the spike was attributable to the solid.

The absence of a doublet structure left us with no basis for determining what the structure of diborane was. Later, after Van Vleck's theory for the second moment was published,¹⁰ we were able to use it to analyze our data and provide some support thereby for the bridge structure. But at the time I saw my thesis project going up in fog with the liquid nitrogen. So I did what chemists have been doing for generations. I made a comparative study of related compounds, ethylene and ethane in this case. Their lineshapes are given in Figure 5. That for ethylene is quite similar to diborane while that for ethane is very narrow. However, our lowest cryostat temperature was at the melting point of ethane (90 K), so to be sure of our results I synthesized some disilane, the silicon analog of ethane which has a m.p. of 141 K, 50 degrees above that of ethane.

Nonetheless disilane also gave a narrow, liquid-like resonance, shown in Figure 5. Up to that time, narrow lines were expected in liquids and broad lines in solids.¹¹ At this stage, however, we finally realized we were seeing a new phenomenon—an averaging out of the dipolar broadening by the hindered molecular motions in a 'plastic' solid. So I switched directions and we started studying the motions. Figures 6 and 7 are a good example of the sort of things we found.¹² Figure 6 compares the width of the proton resonance (lower curve) with the heat capacity in solid 1,2-dichloroethane as a function of temperature. We see that an anomaly in C_p corresponds with a major change in the proton linewidth.

Figure 7 gives the proton lineshapes in the solid at temperatures above and below the heat capacity anomaly. The lineshapes are very similar except that the one at higher temperature is about half as broad as that at lower temperature. A theoretical analysis shows that this corresponds to the proton pairs in $-\text{CH}_2\text{Cl}$ undergoing restricted rotation about an axis perpendicular to the intrapair axis, which no doubt is the *trans*-Cl–C–C–Cl axis. Moreover, the narrowing requires that the reorientations be fast on what is now called the NMR timescale. That is, the reorientation frequency needs to be

Figure 6 Comparison of proton linewidth and heat capacity versus temperature curves for 1,2-dichloroethane¹²

Figure 7 Derivatives of the proton magnetic resonance line observed at 29.0 MHz in solid 1,2-dichloroethane at 90 and 205 K⁹

comparable with the dipolar broadening in frequency units being averaged out. This requires that the correlation time τ_c for the motion be shorter than $\sim 10 \mu\text{s}$ at the C_p anomaly.

In this way I ended up with the second half of my Ph.D. thesis. It was not primarily an NMR determination of the structure of diborane. Instead we discovered a broad range of circumstances where magnetic dipole interactions are strongly coupled to the dynamic state of the chemical species containing the nuclei.^{9,12,13} Also, we showed that dipolar broadening in the 'rigid lattice' at low temperatures could give accurate structural information, in particular a value of 1.025 Å for the N-H distance in the ammonium ion.⁹

STARTING OUT AT ILLINOIS

My joining the faculty at Illinois in September, 1948 was also accidental in character. I wasn't appointed because of the bright future of NMR, but because Roger Adams, the head of the Chemistry Department, needed someone to be responsible for the operation of an infrared spectrometer which the organic chemists had adopted as an essential research service. The instrument was the eighth single-beam infrared spectrometer produced by the Perkin-Elmer Co. during the Second World War, and it and the technician running it required periodic encouragement. My experience with Bright Wilson's homemade spectrometer⁷ overqualified me for the task. So I accepted the appointment at Urbana as an instructor in physical chemistry but with the understanding that NMR would be my main research effort.

At the time I, of course, had no real appreciation of what the future of NMR would bring. I did know enough about physical chemistry, however, to realize that basic new phenomena are not discovered very often. Also, not very many persons have the good fortune to be on the scene at the time of such discoveries. So, blessed with that much good sense, and not inhibited by any real knowledge of electronics or of magnetic theory, I set out to build a broadline NMR spectrometer, such as that which Pake set up at Harvard, but better. Starting up a research program then wasn't too different from what it is now. I had to prepare a proposal and submit it for funds to the University of Illinois Graduate Research Board. They quickly granted me the \$5000 requested, but with the stipulation that I also submit the proposal to Research Corporation. If I received a grant from them, the Research Board funds were to be returned! So I asked for and got \$7500 from Research Corporation and returned the \$5000 to Illinois.

The main item needed was a large magnet. I never seriously considered an electromagnet for the purpose, because I knew it was beyond me and the rudimentary shop facilities then available in chemistry at Illinois, and I wanted to avoid the added operating complexity. These reasons, along with the cryogenic limitations of the 0.75 in. gap in Pake's spectrometer led me to decide on a permanent magnet with a 2 in. gap. Even more important, though I didn't know it at the time, were the efforts I made to attain a homogeneous magnetic field. I did this to avoid problems in locating a good spot for the sample in the field and also to minimize any inhomogeneity corrections to the second moments of the broad lines which were to be studied. So the pole tips were designed with a Rose-type shim to correct for the fall-off in field at the edge of the gap, and high-quality, carefully heat-treated steel was used for the pole tips.¹⁴

My location at the University of Illinois proved advantageous in designing and acquiring the permanent magnet, because two manufacturers of Alnico V permanent magnets were within 200 miles of Urbana. Arnold Engineering Co. in northern Illinois built our first magnet, with a field of 6365 G, which turned out very well. The main problem we had with it was because I had placed no tolerances on the coaxiality of the pole tips in the rectangular, horizontally mounted yoke. The vertical adjustment was fine, because the tips were supported from the bottom of the gap, but the horizontal adjustment proved to be 0.125 in. out of line. We discovered this quite late in the game after spending a couple of months trying to improve the field homogeneity by manually polishing the pole tips, with mixed results. But that's getting ahead of the story.

The magnet was delivered in early October 1949 with a field reported to be 6050 G. On October 20 we saw our first proton resonance in a water sample at 27.1 MHz. However, my original plans to continue studying the motional narrowing of the broad resonances in solids ran into two snags. Our homemade electronics, especially the lock-in amplifier and the preamplifier just after the rf bridge we were using, didn't have the sensitivity needed. Moreover, my initial efforts at designing and building an all-metal cryostat weren't very successful, in spite of having a 2 in. gap in which to place it. Fortunately, Knight's report¹⁵ of the resonance shifts in metals appeared at that time and it included the observation of ³¹P shifts in several compounds. Later, in early 1950, Proctor and Yu reported chemical shifts between the ¹⁴N resonances in the NH_4^+ , CN^- and NO_3^- ions,¹⁶ and Dickinson found shifts for fluorine in

several compounds.¹⁷ These effects were viewed as a nuisance by the physicists who wanted to make accurate measurements of nuclear moments. But they attracted our attention because, first of all, we could observe NMR in liquids, and, second, I felt the shifts must depend in some way on the chemical species involved. So we turned our interests to chemical shifts in fluorine compounds and the beginnings of high-resolution NMR.

HIGH-RESOLUTION NMR

At first we looked at whatever compounds we could lay our hands on. Then we began to see if we could resolve the fluorine resonances from structurally nonequivalent nuclei in the same molecule and on April 26, 1950 we looked at the fluorine resonance in a benzene derivative with a CF₃ group and three fluorines on the ring, and were able to resolve them. This encouraged us greatly and led me to think about how the shifts are related to molecular structure.¹⁸ Chemists learn very early to look for periodicities in the chemical and physical properties of compounds, or they don't stay in chemistry very long. We deal with such a large number and wide variety of systems that we have to oversimplify their diversity to be able to remember them. Moreover, in my senior year at Indiana University I was exposed to Linus Pauling's book, 'The Nature of the Chemical Bond', which is a masterpiece of such oversimplifications. In any case, it seemed to me that the chemical shift, as an electronic phenomenon, should be related in some way to the nature of the chemical bonds. This in turn depends upon the nature of the atoms bonded together, so I chose to study the simple binary fluorides, which was a very happy choice.

I was encouraged in this approach, because at about that time I acquired my first graduate student, Charles Hoffman, who was interested in and very good at inorganic synthesis. He undertook to synthesize the fluorides needed for the study, many of which were difficult, and he measured their fluorine shifts. At this juncture, in May 1950, good fortune favored me again. I found exceptionally able help with our electronics problems from R. E. McClure a senior in electrical engineering, who worked part-time with my group while he finished his bachelor's and master's degrees.

Bob was an immediate help, not only in maintaining, designing, and constructing our apparatus, but in running many of the early experiments. With his able help, we set out to see if we could find shifts in proton resonances. We convinced ourselves of them on June 30, 1950, when Bob found small but reproducible shifts, several times larger than experimental error, between the protons in benzene, mineral oil, and aqueous solutions of strong acids.¹⁸ At this stage, we started a major effort on improving the homogeneity of the magnetic field by plotting it and hand-polishing the pole tips in those areas where the field was high. And later, we broadened the shift study to include the simple hydrides. A block diagram of the sort of early high-resolution spectrometer we used in these measurements is given in Figure 8.

The shifts found for the fluorides are shown in Figure 9 where they are plotted against the electronegativity of the atom bonded to the fluorine.¹⁴ There is an approximate linearity, with ionic fluoride the most highly shielded and the most covalent fluorine (F₂) the least shielded. I later challenged

Figure 8 Block diagram of an early (1951) high-resolution NMR spectrometer

Figure 9 Fluorine chemical shifts in binary covalent compounds versus the electronegativity of the atomic species bonded to the fluorine.¹⁴ Larger values of δ are upfield shifts

Apollo Saika, a student from Japan, to account for this strong correlation and he and Charlie Slichter came up with their elegant paper¹⁹ attributing it to the second-order paramagnetic term of Ramsey's theory²⁰ and its dependence upon the p-electron bonding orbital of the fluorine. The shifts for protons are more complex, as may be seen in Figure 10, depending markedly on the Group of the partner element. Also, their range is 60-fold smaller than for fluorine. Both differences stem from the s-electron bonding for hydrogen and p-electron for fluorine.

In our study of the fluorine shifts we came upon a new phenomenon—the indirect coupling of nuclear spins or the spin-spin coupling as it is often called. Independent work by several groups was needed for its unraveling.^{16,21–30} The story is an interesting illustration of just how difficult it is

Figure 10 Proton chemical shifts in binary covalent hydrides versus the electronegativity of the atomic species bonded to the proton (Ref. 14). Larger values of δ are upfield shifts

to accept something really new even when you see it. In my lab, the first observation of the effect was by Charlie Hoffman on September 8, 1950. In measuring the fluorine resonance of the small sample of PF_3 he had synthesized, we found two close lines of comparable intensity. They were attributed to what we knew, to a chemically shifted impurity, probably PClF_2 or PCl_2F from the preparation. Hoffman repurified the sample, but the second line wouldn't go away. So another preparation route was tried but the new product gave the same fluorine doublet. During this period PF_5 was synthesized and the fluorine resonance was found to be a double line. This time we could not ignore the equal intensities of the two lines and attribute them to a chemical shift between the three equatorial and two apex fluorines of the trigonal bipyramidal structure, which it wasn't. The effect remained a mystery for four months.

It wasn't until March 1951 that it became completely clear we were really seeing something entirely new. At that time I encouraged a beginning graduate student, Dave McCall, to look at some phosphorus shifts in several fluorochloro phosphorus compounds of known purity, which I scrounged from Don Martin then on the inorganic faculty. When the ^{31}P resonance in the POCl_2F compound exhibited a 1–1 doublet structure, it finally dawned on me that we had been observing a new type of spin–spin interaction. In it the splitting of the fluorine resonance depends on the number of different phosphorus spin states (2) while splitting of the phosphorus resonance depends on the number of different fluorine spin states (also 2).²² It was a great thrill for Dave and me when shortly thereafter we first saw a ^{31}P resonance such as that reproduced in Figure 11 for Me_3OPF_2 , a 1–2–1 triplet caused by the two equivalent fluorines, as predicted.

In the meantime Erwin Hahn had observed 'slow beats' in the spin echo envelope for nonequivalent protons.²⁴ This led

Figure 11 Oscilloscope photograph of the phosphorus resonance observed in liquid Me_3OPF_2 at 25.5 MHz³⁰

me and Charles Slichter's group to explore the relationship between the steady-state multiplets and the modulation of the spin echo envelope. We found that the fluorine spin echo envelopes of BrF_5 and IF_5 (tetragonal pyramids) exhibited a slow beat frequency corresponding to the steady-state (first-order) multiplet splitting of the apex and equatorial fluorines.²⁵ Comparison by Hahn of the proton spin echo modulation²⁶ with the steady-state splittings²⁷ was more difficult because of second-order effects caused by the small proton shifts. But it later led²⁴ to the same conclusion—only one interaction was involved.

Thoughts about the nature of that interaction started with the familiar. The first 'multiplet' was published by Proctor and Yu.¹⁶ They reported the ^{121}Sb and ^{123}Sb resonances in an aqueous HF solution to be symmetrical multiplets and suggested the cause might be the Sb–F magnetic dipole–dipole interactions, incompletely averaged out by hindered rotation.¹² Andrew²¹ made a theoretical analysis of this model. This was tested in a repeat of the experiment.²⁹ The results were incompatible with hindered rotation but in agreement with the 'multiplet rules'.

Along the way it was recognized^{23,26} that the mathematical form of the interaction must be $A_{12}\mu_1\mu_2$ with A_{12} a coupling constant related to the electronic structure of the molecule. A general theory was developed by Ramsey and Purcell²⁸ for the coupling constant, attributing it to an indirect interaction between the nuclear spins via their magnetic polarization of the electrons. Slichter showed that this approach predicted coupling constants in reasonable agreement with our early experimental results, primarily on phosphorus compounds with P–H and P–F splittings.³⁰

Motional narrowing, chemical shifts, and the spin–spin coupling are the phenomenological basis of high-resolution NMR. It remained to be discovered how useful it is. A major step in this direction was taken by Lee Meyer in 1952 with a new high-resolution spectrometer built by our group.³¹ Lee made a survey of the extent to which proton shifts are characteristic of the various functional groups in different organic compounds. This approach, in which he was later joined by Apollo Saika, reflected my supervision of the Perkin-Elmer infrared spectrometer which was the cause of my being hired at Illinois. In the course of that service work, I had become impressed by the extent to which various functional groups absorbed at characteristic vibrational frequencies in the infrared region and I thought it important to try the same thing for proton shifts. I presented the results at a meeting of the American Chemical Society in Chicago in the fall of

Figure 12 A chart of the proton chemical shifts observed for various functional groups in different compounds³¹

1953. They are summarized in Figure 12.³¹ The horizontal bars indicate the range of shifts found for each functional group, the number of compounds observed for each group being given after the group's formula.

By that time Varian Associates had built two or three high-resolution spectrometers on special order for several of the oil companies, but the market was then very limited. In fact, Martin Packard confided to me much later that at the time of the Chicago meeting Varian Associates was about ready to drop their NMR program as unprofitable, or at least the high-resolution part of it. Whatever the case, the results shown in Figure 12 did foreshadow some of the promise which high-resolution NMR has since fulfilled and encouraged Varian to continue the development of applications.

EXCHANGE AVERAGING IN HIGH-RESOLUTION SPECTRA

During the course of characterizing the spin-spin coupling we became aware of the fact that 'fast' chemical exchange can average out the splittings. For example we found a fluorine doublet in solutions containing the PF_6^- anion but not in HF. Another case was that of aqueous HBF_4 , in which the proton and fluorine resonance widths were instrumentally determined, at about 0.01 G, while that of ^{11}B may have been somewhat larger. ^{11}B has a large g -value, so we expected to resolve a splitting of the fluorine resonance as in aqueous HPF_6 . But we didn't. After a great deal of debate, we attributed the absence to chemical exchange of fluorines among the BF_4^- ions. This led Charlie Slichter to develop a mathematical treatment, based upon the Bloch equations, of the exchange effects.³⁰

The results prompted a more deliberate search for definitive examples of the phenomenon. The first of such studies was by Apollo Saika, who in 1952 looked at the concentration dependence of the proton shifts in aqueous strong acids.³² The fast proton transfer in such systems puts them in the fast exchange limit, so exchange rates could not be measured, only the concentration-dependent average shift. In addition,

Figure 13 High-resolution NMR lineshapes as a function of exchange lifetime, τ , between two equally populated sites separated by $\delta\omega$ in the absence of exchange³²

Apollo calculated (by hand in those days) a set of lineshapes in the intermediate region between fast and slow exchange for the equally populated two-site case. The results are given in Figure 13 as a function of τ , the exchange lifetime. In the slow exchange limit, the resonance is a doublet; in the fast exchange limit, a central singlet.

These lineshapes led me to suggest that rather short chemical lifetimes in the range of 10^{-2} – 10^{-4} s could be measured by such an approach. I even was bold enough to propose³² that 'a combination of temperature and magnetic field changes in the transition region would permit evaluation of the activation energy for the exchange'. Reduction of this to practice was delayed by the difficulty of finding suitable systems with exchange rates in the right region. At that time there just weren't other methods for measuring reactions with half-lives in the millisecond range, so no known suitable examples were available for us to study via the proposed new method.

Moreover, the discovery of an appropriate system for study was delayed for several years because at first it wasn't recognized as such. This is of course the now classic example of the *N,N*-dimethylamides (1) and (2), which when pure have at room temperature a close doublet from the two *N*-methyl groups. The structure is as shown below. One of the methyls is *cis* to the C=O group at the other end of the molecule, while the second methyl is *trans*, so they have chemically shifted lines. Furthermore, the partial double-bond character of the central N–C bond hinders internal rotation about that bond and prevents exchange narrowing of the shift at room temperature.

Lee Meyer in the survey of proton shifts did observe a double *N*-methyl resonance in *N,N*-dimethylformamide.³¹ However, it wasn't a very 'clean' doublet, perhaps because

traces of acid and base catalyze the exchange and tend to average it out. In any case, a chemically shifted doublet was not expected by Lee and when a poor one appeared it was shrugged off as an instrumental and/or impurity effect. But a couple of years later, after Phillips reported seeing it at room temperature,³³ the compound impressed me as a very likely candidate for a temperature-dependent rate study by NMR methods. A graduate student, Chuck Holm, became interested in this possibility and, after improving the spectrometer, he made a successful study of the internal rotation rate in amides as a function of temperature, through the coalescence transition from slow to fast exchange. His results³⁴ are crude by today's standards but they did give reasonable values for the exchange rates and enabled the activation energy to be determined. They were good enough to encourage the use of NMR in a wide variety of exotic conformational exchanges.

CONCLUSION

The initial decade of NMR, from 1945–55, was a tremendously exciting period of discovery in magnetic resonance, not only in NMR but also in ESR and pure quadrupole resonance. Moreover, the numbers of scientists then engaged in such research was small, so it was possible to keep up with what was going on. There was a club-like atmosphere to the field. It was great to be a participant in some of the more chemically oriented research during this period.

As a chemist I was accustomed to looking at different chemical species. And in those days it seemed that every new compound you tried turned up a new phenomenon. In reminiscing about the good old days, I've tried to describe how subjective and personal factors can change the course of science and also, how important it is to determine whether the unexpected result is an artifact, a nuisance, or something really significant. And for the newcomer, looking for yet another exotic phenomenon in the field, I quote from the 1980 review article³ which still holds, 'NMR is a true evergreen'.

Haeberlen, Ulrich: The Early Days of Multiple Pulse NMR

Ulrich Haeberlen

Max-Planck-Institut für Medizinische Forschung, Heidelberg, Germany

In the summer of 1967 I received a fellowship from the Deutsche Forschungsgemeinschaft to undertake postdoc work with John S. Waugh at MIT. After having crossed the Atlantic by ship(!), I arrived in Cambridge, MA in the fall and when I arrived it was already there. The idea. The idea that and how the line broadening in solids caused by homonuclear dipolar couplings of the spins could be suppressed. The witchcraft to accomplish that feat were sequences of rf pulses of special, well-defined phases and delays. No doubt it was John's idea. Clearly, it was something fundamentally different from spin locking. It was going to retain *spectral* information.

It required a pulse spectrometer capable of firing 90° pulses in rapid succession. 'Rapid' on the timescale of the decay time T_2 of the free induction decay (FID) of a solid meant 20–30 μs . Within T_2 , four pulses with mutually orthogonal rf phases and spaced by delays $\tau-2\tau-\tau-2\tau$, etc. should hit the sample, the extra condition being that the NMR should be picked up between the pulses on the flight. Lee Huber was working hard to build a spectrometer to satisfy these requirements. The central piece of his equipment was an (always drifting) Varian '60 MHz' high-resolution 12-in. magnet. It was sitting in the center of a basement room of the MIT Chemistry Department. In those days NMR labs were always banished to basement rooms because of the weight of the magnet.

John didn't know much about me except that as part of my Ph.D. thesis I had built a pulse spectrometer and that I boasted it had one of the shortest, if not *the* shortest, recovery time of any current pulse spectrometer. A short recovery time was urgently needed for the new experiment. So, logically, John suggested I should assist Lee. He assigned me a desk in the room with the 12-in. magnet. On 'my' desk there was naturally (as I now know) a heap of junk. The first thing I did, naturally enough in my opinion, was to find another place where I could pile up all the junk, and to clean up and to clean my desk (it was also full of dust). When John noticed that he beamed and remarked: Aha, Germans need Lebensraum. He said 'Lebensraum' in German. Obviously I had just acted like a Bilderbuch German.

In those days a pulse NMR spectrometer was quite different from what it is today. The signal detection path consisted usually of only an rf amplifier and an oscilloscope which served for displaying the FID or the spin echo. There was no computer and, ipso facto, no software [which is now considered by many as the most important part of the spectrometer—original quotation (1985) of a Varian representative]. Remember the famous Ernst–Anderson paper on Fourier transform NMR had only appeared in the preceding year and neither mini- nor microcomputers existed as yet. A typical pulse spectrometer was then designed to perform FID and the Carr–Purcell–Gill–Meiboom echo train and, perhaps, spin-locking experiments. For this reason it comprised

two rf channels with a mutual 90° phase shift and a pulse programmer that could generate a 'preparation' pulse and then a burst of radiofrequency or a sequence of other pulses whose width and spacing could be adjusted. With such a spectrometer one could not undertake the 'line-narrowing' four-pulse experiment we had in mind, but the extensions needed were straightforward: instead of two rf channels we needed four, and the pulse programmer was required to generate not only one but two separate delays in a ratio of 2 : 1. On the detection side it was clearly not sufficient to observe the NMR signal directly at the Larmor frequency. A *phase sensitive detection* was called for. Thinking back, I now find it strange that phase sensitive detection did not strike me as a kind of revelation—I, who until then had always observed FIDs and echoes either directly at the Larmor frequency or by diode detection. As far as I recall, it really did not. Actually it was simple to implement because Hewlett Packard had just started to market double balanced mixers which could do the job in an elegant manner. Building the pulse programmer was particular fun because it gave us the opportunity to play with the newly introduced integrated circuits—the DTL logic family! (No mistake, DTL, *not* TTL.)

In any event it did not take long before Lee and I got the spectrometer ready for the first line-narrowing multiple pulse (mp) experiment. Again, I now find it strange that there was absolutely no discussion about the kind of sample we should take for trying it out. Of course it had to be a single crystal of calcium fluoride, CaF_2 , oriented such that its (111) crystal axis pointed along the applied field B_0 . In those days CaF_2 was *the* NMR *drosophila* for all experiments testing propositions about homonuclear dipole–dipole interactions. We knew that for (111) along B_0 the fluorine FID of CaF_2 had a first zero crossing at 52.3 μs . [For (100) along B_0 it occurs after 19 μs .] In the beginning we could make τ equal to 6 μs , but not shorter. A full 'cycle' lasted 6τ , i.e. 36 μs and we knew that this time, called the 'cycle time', had to be much shorter than T_2 . Now, 36 μs is not *really* much shorter than 52.3 μs and this latter time is not for T_2 but for the first zero crossing! Hence we were quite anxious about whether or not the experiment would work.

It worked. It worked remarkably well, so well that before the end of the year we had submitted a letter to *Phys. Rev. Letters*. It appeared in the issue of 29 January 1968. With a sample-and-hold circuit and a Fabri-Tek 1062 signal averager we had 'sampled' the NMR signal once per cycle during an mp train of about 200 cycles. We had punched the record of samples into IBM punch cards—one sample per card—and had it Fourier transformed in the MIT computer center. We had added to the sample of CaF_2 a small amount of liquid $\text{C}_6\text{H}_5\text{CF}_3$ to demonstrate that 'our' sequence was able to resolve chemical shifts (albeit scaled down by a factor of $1/\sqrt{3}$). While preparing this article I looked again at this first mp Fourier-transform spectrum. I now recognize that it must have been the *power* spectrum of our mp record of samples. I wonder whether back in 1967 I was aware of the difference between a *power* and an *absorption* spectrum. John was, I am sure. Nowadays I disdain power spectra. No matter whether it was a power spectrum or not, it marked the coming into existence of *high-resolution NMR in solids*.

Of course there were precursors. G. Siegle in Stuttgart (1966) and the British NMR groups around J. G. Powles, P. Mansfield, and J. H. Strange (1962, 1963) had produced

spin echoes from strongly dipolar coupled solids. Their pulse sequences differed from the Hahn echo sequence in two respects: the second pulse had a phase shift of 90° with respect to the first one and, for producing the largest possible echo, it had to be a 90° pulse. An echo appeared *only* if the second pulse was fired *before* the FID generated by the first had decayed to virtually zero. These experiments had demonstrated that the fast decay of the transverse magnetization of a dipolar coupled solid is not a totally irreversible process. Ostroff and Waugh (1966) and Waugh and Huber (1967) had taken another important step forward: they had subjected the spin system to a whole string of pulses and had followed its time evolution ‘in one shot’. They had also formulated the eventual goal of line-narrowing mp spectroscopy: measuring small chemical shifts in the presence of strong dipolar couplings. Their sequence allowed them just to touch this goal: when, as a result of the chemical shift, the magnetization had nutated by roughly 90° , the mechanism of suppressing the dipolar line broadening ceased to be effective. Then there was the famous, often-quoted Lee–Goldburg experiment (1965). It had demonstrated that by setting up an effective field B_{eff} in the rotating frame which subtends the ‘magic angle’ with the applied field B_0 , it is possible to keep alive the precessing magnetization of a solid for a much longer time than T_2 .

All these precursors of line-narrowing mp spectroscopy have their due place in the history book of NMR, nevertheless they all remained experiments which, in essence, were undertaken only once. They never took the decisive step of becoming a *method*, a method for *measuring something*. Another important precursor, the magic angle sample spinning (MASS) experiment of Andrew, Bradbury, and Eades (1958), and Lowe (1959) eventually took this step after having had a dormant phase of nearly two decades and having undergone a metamorphosis during which abundant ^{23}Na and ^{31}P had transformed into rare ^{13}C and ^{29}Si nuclei.

The unique *something* which the mp line-narrowing method promised to make amenable to measurement—and eventually did—was the shielding tensor of protons and ^{19}F nuclei. This was clear to us from the very beginning, but it took us almost a full year before at last we could record an mp spectrum from a solid with two separate resonances and with one of them displaying even a feature which the loving eye could recognize as a chemical shift anisotropy powder pattern. Actually we were not very proud of it and John thought we had better hide it in *Polymer Letters*. By that time Lee had received his Ph.D. and Dave Ellett had joined the team. Rather than looking for real applications we spent our time on ‘inventing’ and analyzing variants of the four-pulse sequence and on developing a theory suitable for describing these ‘experiments’ (as we called them). The theory is now known as *Average Hamiltonian Theory* and it is a pleasure for me to take this opportunity to acknowledge its first germ: it is W. A. B. Evans’s Report 881 issued by the Materials Science Center of Cornell University. He wrote on ‘Some Applications of the Magnus Expansion in NMR’. In February 1968 John had received a typewritten preprint which he showed me. It is this paper which acquainted me with the Magnus expansion.

The predominance of theory and the development of new line-narrowing mp sequences over actual measurements of shielding tensors lasted until the early 1970s. In the meantime the Nottingham and the Caltech NMR groups around P. Mansfield and A. N. Garroway, and R. W. Vaughan, W.-K.

Rhim, and D. D. Elleman (and, somewhat later, D. Burum), respectively, had joined the MIT group in its efforts in developing high-resolution NMR in solids. Soon the group in Jena around G. Scheler, H. Rosenberger, and B. Schnabel joined the mp NMR club. We were all friends and, frankly speaking, at the same time fiercely jealous competitors. Jealousy has died away over the years, friendship survives. We all mourn the tragic deaths of our friends Robert Vaughan (25.5.1979) and Hans Rosenberger (9.3.1989).

In September 1969 I returned to the old continent by plane. Ocean liners were out of business. Karl Hausser—I am still very much obliged to him—had offered me the opportunity to set up an mp NMR lab in his department at the Max-Planck-Institut für Medizinische Forschung in Heidelberg.

When I arrived it was already there. The minicomputer. It was a French model, un ordinateur CII 10010, and had cost the German taxpayer a fortune, about the equivalent of a comfortable home including the garden. It had a magnetic core memory of 16 kbytes and no operating system whatsoever. It came with an assembler which had to be loaded from a punched paper tape. The loading with a teletype took 20 min. Every syntax error led to a fatal crash and the assembler had to be reloaded. It was completely useless and Alfred Döhring eventually did all the programming in machine language.

The 10010 had two wonderful features. The first was the direct memory access. By pulling (asynchronously) one line, called CYEX, it would hand over to the external device the control of the address and data lines within at most three clock cycles of 500 ns, i.e. within $1.5\ \mu\text{s}$. I still wonder how the 10010 did it because it implied suspension even of running microprograms—they continued properly after the external device had returned the control to the machine. A response time of $1.5\ \mu\text{s}$ was fast enough for acquiring mp data with just a sample-and-hold circuit and an 8 bit, 1 megasamples s^{-1} , 7000 DM analog-to-digital converter between the spectrometer proper and the 10010. The other feature which I greatly appreciated was that I always knew in which physical core a given data bit was stored. When after about 10 years we sent the 10010 into retirement, it took me a long time to accept that such a mysterious thing as an operating system could be trusted to handle the data storage.

Apart from the minicomputers, the early 1970s brought another important change to the mp field: inventing and analyzing pulse sequences gradually moved to the back of the stage and ‘real’ applications came to the limelight. In 1971, M. Mehring, R. Griffin, and J. S. Waugh recorded and published ^{19}F mp powder spectra of a number of perfluorinated compounds. These spectra allowed the reliable determination for the first time of the principal components of ^{19}F shielding tensors. In the same year L. M. Stacey, R. W. Vaughan, and D. D. Elleman reported the first single crystal measurements of complete shielding tensors including the principal directions.

By 1973, the time had come for applying the mp line narrowing technique to the measurement of proton shielding tensors (Haeberlen and Kohlschütter, 1973). This is the point at which, to recall that, in 1969, D. C. Haddix and P. C. Lauterbur had measured in a straightforward way the proton shielding tensor in trichloroacetic acid using a 100 MHz spectrometer. At this frequency and in this particular compound, the proton shift anisotropy is larger than the dipolar linewidth. For proton mp spectroscopy, we in Heidelberg had an advantage over our competitors at MIT, Caltech and Nottingham: our spectrometer

was operating at 90 MHz, whereas the MIT and Caltech groups still worked at 54 MHz while the Nottingham group did its mp research at 'only' 9 MHz.

The first occasion where members of all the mp NMR groups met and reported on the state-of-the-art in their labs was the 1st Specialized Colloquium AMPÈRE in Krakow in 1973.¹ High-resolution NMR in solids was the dominating theme and also the title of the opening lecture delivered by E. R. Andrew. John Waugh and Alex Pines spoke about the PENIS experiment, and Paul van Hecke presented the mp work of MIT. He showed spectra and chemical shift rotation patterns of single crystals of anhydrous oxalic acid, $(\text{COOH})_2$, and explained how the proton shielding tensors could be extracted from such data. It is important to remember what a judicious choice anhydrous oxalic acid was: the compound contains protons as the only magnetic species (forget the rare ^{13}C nuclei); all the protons are crystallographically equivalent; the proton shielding anisotropy is 'large' (≈ 20 ppm); and crystals can easily be grown. (Later on Paul spent a year in Heidelberg and did a beautiful experiment on KHF_2 with simultaneous homo- and heterodecoupling.)

I was particularly anxious about what Bob Vaughan was going to report, because shortly before the conference his group (Rhim, Elleman, Vaughan, 1973) had introduced the line-narrowing sequence which is now known as the MREV sequence. The 'M' in the acronym stems from Peter Mansfield who, in a notation which nobody except himself understood at the time, had already proposed it in 1971. I was anxious because I knew that Bob had just obtained fantastically long-lasting mp decays from CaF_2 with that sequence. In his talk, however, Bob went so hastily over these intriguing results that people suspected he was not quite sure of them. As a matter of fact only recently have I come to feel that after all they may have been real.² In any event the climax of Bob's talk was a proton mp spectrum of a powder sample of trichloroacetic acid. It demonstrated a down-to-earth spectral resolution.

I reported on measurements of the proton shielding tensors in oriented single crystals of malonic acid. I was particularly proud of the data from the CH_2 group because that group was considered a difficult case—strong dipole–dipole couplings and a small shielding anisotropy. U. Haubenreisser and B. Schnabel from Jena had investigated the shielding anisotropy of the crystal water in kieserite, $\text{MgSO}_4 \cdot \text{H}_2\text{O}$ and M. Mehring, then in Dortmund, and his student H. Raber demonstrated what a true solid state physicist and NMR spectroscopist should do: apply the newly discovered technique to metals. They had refined the values of the Knight shifts in aluminum and beryllium. And Peter Mansfield, what did he talk about? He began with reflection symmetry in mp sequences but soon turned to NMR diffractometry. In retrospect he talked and speculated about spin imaging and actually showed pictures of phantoms! Literally nobody took him seriously. What a mistake.

Back to mp NMR. It continued to mature and soon became the method for measuring proton shielding tensors. In 1977 I was invited to give a talk at the NMR Gordon Conference. I chose the title: 'Harvesting Time in Multiple Pulse NMR'.

In 1975 I had written a chapter on 'High Resolution NMR in solids; Selective Averaging' for *Advances in Magnetic Resonance*.³ It was too long for a chapter so it became a separate volume and Supplement 1 of this series. John was kind enough to write a foreword. He expressed his belief that

Figure 1 Progress in mp NMR. ^1H spectra of a single crystal of malonic acid. The full width at halfheight of the two resonances on the left of the 1990 spectrum is 45 Hz, corresponding to 0.4 ppm

this volume represents the last word on the subject. I feel proud of this assessment but likewise I am happy that John turned out to be wrong. The ideas developed along with the advance of mp spectroscopy have greatly influenced other and unforeseen areas of research. I restrict myself to mentioning the creation and detection of multiple quantum coherences. Line narrowing by mp sequences combined with magic angle sample spinning, a technique now known as CRAMPS, has become the method of choice when solid state proton NMR is used for *analytical* purposes. This possibility was initially mentioned in our *Phys. Rev. Letter* in 1968. After the great success of NMR imaging in medicine, people naturally turned to NMR imaging of solids and of course used mp sequences for narrowing the resonances. But even mp spectroscopy in the narrow sense of the word had not come to an end in 1976.

In 1979 D. P. Burum and W.-K. Rhim introduced their 24 and 52 pulse cycles.⁴ While the latter is too long to be practical, the former has become one of the standard mp sequences. In a recent article² we wrote that its line-narrowing capacity has probably never been fully exhausted in actual experiments. The resolution of state-of-the-art mp spectra is no longer limited by residual dipolar broadening. Progress must now come from seemingly trivial matters such as sample handling.

In Figure 1 we present a series of mp spectra for a single crystal of malonic acid which documents the progress of mp spectroscopy with time. The three older spectra appeared initially in 19855 and M. Munowitz was kind enough to reproduce them in his book entitled 'Coherence and NMR'.⁶

We are glad we can now add a fourth. Ralf Prigl recorded it in 1990. In 1994, Bernd Tesche has studied crystals which give rise to as many as 12 lines in the proton mp spectrum and he claims to be able to measure the components of proton shielding tensors to within ± 0.1 ppm.

Hägele, Gerhard: Analysis and Simulation of High-Resolution 1D NMR Spectra. Some Steps Closer to Automation

Gerhard Hägele

Heinrich-Heine-Universität, Düsseldorf, Germany

Intuitive understanding of complex second-order spectra and the computational analysis and simulation of high-resolution 1D NMR spectroscopy has intrigued us for many years. This interest was encouraged by R. K. Harris in Norwich when we studied the ^1H and ^{31}P NMR spectra of symmetrical phosphorus compounds such as $[\text{CH}_3(\text{C}(\text{CH}_3)_3\text{P}(\text{X}))_2\text{Y}]$ ($\text{X} = \text{O}, \text{S}$; $\text{Y} = \text{—}, \text{O}, \text{S}$). Algebraic equations for transition frequencies and intensities of $[\text{AR}_i\text{X}_n]_2$ spin systems and the programs DOK178 and DOK177 were developed to simulate the R_i and X_n or A spectra. Later on a more general treatment for spin systems holding n_g groups in

$$\left[A \sum_{i=1}^{n_g} X_{ni}^i \right]_2$$

was derived.

For analyzing the ^1H and ^{19}F NMR spectra of $\text{CH}_2\text{FCHFCO}_2\text{CH}_2\text{CH}_3$ (superpositions of ABCXY and ABC₃), LAOCOON and UEANMR programs for single spins and composite particles consisting of spins $I = \frac{1}{2}$ were used. Decoupling the protons of cyclobut-1-ene-1,2-bis(phosphonic acid) tetramethyl ester (**1**) by $^{19}\text{F}\{^1\text{H}\}$ and $^{31}\text{P}\{^1\text{H}\}$ led to an $[\text{A}[\text{X}]_2]_2$ spectrum involving the chemical equivalence of single spins in a twofold symmetry which was tackled with LACX. The nondecoupled ^1H , ^{19}F , and ^{31}P NMR spectra of this compound bear the full complexity of the combined chemical and magnetic equivalence in $[\text{AM}_6[\text{X}]_2]_2$ systems with spins $I = \frac{1}{2}$ and were dealt with by NUMAR and NUMARIT programs. (A review of program development and references up to 1987 are given in Ref. 1)

My interests concentrated on fluorine compounds and corresponding spin systems, e.g. pentafluorophenylsilanes $(\text{C}_6\text{F}_5)_n\text{Si}(\text{CH}_3)_{4-n}$ ($n = 1-4$) (approximately $[\text{A}[\text{BC}]_2]_n \text{X}_{3(4-n)}$), 1,3,5-trifluorobenzene $[\text{AX}]_3$, and octafluoronaphthalene $[\text{AB}]_4$, which created demands for spectral simulators and iterators capable of higher symmetries for fast

calculations of greater spin systems. Based on the projection operator technique, the most general forms of chemical and magnetic equivalence were combined in simulators DSYMPLOT¹ and DCYMPLOT¹ (QCPE), two FORTRAN IV programs for mainframe computers. Iterative versions were not based on the explicit line assignment technique of Castellano/Bothner-By/Braillon since the total lineshape approach was more appropriate. The iterative core of G. Binsch's DAVINS was extracted, modified for faster convergence and supported by simulators DSYM and DCYM to yield a set of programs¹ SPECPRP, DAVSYM1, DAVSYM2, DAVCYM1, and DAVCYM2 (QCPE). Streamlined FORTRAN versions were combined in to a package DAISY,¹ available for mainframe computers and workstations, e.g. the Bruker X.32 computer.

With the advent of PCs and the descent of computing centers, it was imperative to develop fast algorithms and the easy-to-handle menu-driven programs DSYMPC² and DCYMPC² for simulations on PCs. Early DOS limited the systems to 8 spins and the Lorentz plots to 2k data points. Iterations on PCs still proved to be slow at this stage. A major breakthrough came from several points of view: algorithms for QM calculations and Lorentz generation were thoroughly reformulated and implemented in C++. Easy data input was achieved via WINDOW techniques. In particular, the input of the symmetry description was simplified to set up permutational operators automatically. A novel and efficient iteration concept was introduced in cooperation with C. Witsch, B. Neeb, and H. W. Höffken (Mathematics, Düsseldorf). These sources were designed to run on PCs 486 under WINDOWS as WIN-DAISY using WIN-NMR (Bruker). The program WINDAISY³ is able to handle composite particles of spins $I \geq \frac{1}{2}$ in isotropic and anisotropic phases. The full Hamiltonian was installed involving intra- and intercomposite particle dipolar coupling constants. The ^{19}F NMR spectrum of $\text{Hg}(\text{CF}_3)_2$ ³ in nematic solution including the ^{199}Hg satellites was dealt with successfully.

Due to dynamic programming, the maximum number of spins n_s in the system is limited for 32-bit computers to $n_s! \leq 2^{31} - 1$. Future 64 bit computers will allow $n_s! \leq 2^{63} - 1$. At present a maximum of 12 spins in 10 groups is allowed, e.g. $\text{A}_3\text{BCDEFGHIJ}$. Further progress is achieved by 'chemical factorization' of isolated 'spin islands'. For example, benzoic acid phenyl ester may be handled using two different concepts: (a) as a 10-spin spectrum with zero inter-ring coupling constants or (b) as two overlapping five-spin spectra obtained from two consecutive simulations. Model (a) requires 5 min and (b) 2 s for calculations, which corresponds to an acceleration factor of 150. This MEGASIM principle might be useful for overlapping spectra, e.g. in peptide chemistry. Iterations of a singular phenyl $[\text{BC}]_2$ spectrum require 2 min while 10-spin problems need about 28 h.

The method of total lineshape analysis has solved many intricate spin systems with start parameters reasonably far from the final data, but no mathematical method exists to predict reliably the iterability of specific problems. There are 'bad' cases, especially when very sharp lines with an insufficient number of data points per halfwidths occur. In addition, if essential information is hidden in frequencies connected with low intensities, then explicit line assignment, preferably supported by R. Laatikainen's automation in PERCH,⁴ may help. On the other hand, the line assignment will fail in a

multiline system with an overlap of broad lines. Consequently, future developments will combine both optional approaches supported by structural and numerical data banks to obtain reasonable start parameters for fast iterations.

To support the analysis and simulation of HR 1D NMR spectra, auxiliary programs have been designed: MINILA² (teaching QM in NMR), NMDR² (Double Resonance) and SPINA-AT.² The latter program covers the classical literature on explicit solutions for transition frequencies and intensities given for two to four spins and some composite particle problems. The input of experimental frequencies (in some cases intensities) will yield results from direct and subspectral analysis. The parameters obtained may be iterated on-line to yield optimized data. Finally, a brute force method of spectral analysis was developed: NMRFILM.² A simulator is placed inside nested DO loops varying frequencies and coupling constants from lower to upper limits and producing a film-like sequence of NMR spectra on the PC monitor. Ocular inspection leads to the best parameter combination.

Hahn, Erwin L.: Pulsed NMR—A Personal History

Erwin L. Hahn

University of California, Berkeley, CA, USA

INTRODUCTION

The personal history which follows is concerned with a limited number of my researches in pulsed NMR. It outlines some of the circumstances, early ideas, and false starts which led to the final result. Because of space limitations, my account includes only those individuals and institutions locally connected with the described experiments. I regret that I have had to omit extended reference to many other of my students and colleagues who have had great influence on me. I am indebted to them, as well to those appearing in this history, for all that I have learned in pursuing my researches.

UNIVERSITY OF ILLINOIS, 1946–50

As a beginning physics graduate student in 1946 at the University of Illinois, I was a research assistant to the betatron development program headed by D. W. Kerst. I entered this program with some background experience in radar and sonar electronics as a technician in the Naval Reserve during World War II. Not particularly enamored of participating in big machine physics, I decided in 1948 to change to another field for a thesis subject. Prof. James H. Bartlett, a theoretical physicist, suggested that I should switch to ‘small science physics’ and start by reading the pioneering NMR papers by the Bloch¹ and Purcell² groups at Stanford and Harvard. There was no NMR specialist in the Illinois Physics Department faculty at that time who could guide a thesis in this new field. However, with the umbrella support of an ONR Physics Department block grant, I was allowed to forge ahead on my own with the help of a skilled technician to build a copy of the Harvard CW NMR rig. I remember with gratitude the benevolent support of Physics Department Chairman F. W. Loomis, who appropriated funds for me to visit the Harvard NMR laboratory of Pound, Bloembergen, and Purcell and to talk with them.

In the beginning I had no idea about what I wanted to measure with my newly constructed apparatus. I was happy just to see a signal from protons. About the same time, Herb Gutowsky came from Harvard and joined the staff of the Illinois Chemistry Department. With the NMR experience acquired at Harvard, Gutowsky carried out pioneering NMR experiments which initiated the field of structural chemical analysis. Charlie Slichter also came from Harvard and joined the Physics Department about a year later. In particular the NMR doublet and lineshape work by George Pake³ and the technique of linewidth analysis by the Van Vleck method⁴ of diagonal sums came out of Harvard as new developments, very important for CW solid state and chemical analysis.

As I remember, I interacted only casually with Herb, not close enough to follow or really understand in depth what he was doing. I felt I was an ignorant peasant graduate student, preoccupied with learning the rudiments of NMR. Herb asked me what I was going to do with the rig I built for my physics thesis. By the time of his query I had cooked up a vague idea that perhaps I could follow the progress of a chemical reaction, maybe by looking at the changes in relaxation times in liquid systems. I decided I needed experience first by measuring relaxation times in the time domain using a pulse saturation method. Why did I choose of all things the heretical subject of measuring the ‘progress of a chemical reaction’ for a graduate physics thesis? The reason: my undergraduate degree was in chemistry, so that was about the only original thing I could think of at the time.

Spin Echoes

After reading the published thesis⁵ of Nico Bloembergen, which contained an analysis by J. Schwinger of the nutation effect, often referred to as the ‘Rabi flop’,⁶ I dropped the fuzzy idea of measuring a chemical reaction and decided to measure instead the nutation dynamics of protons in the rotating frame. Spin nutations had never been seen directly by NMR in condensed matter. The experiment appealed to me because it required the application of rf pulses. Pulse techniques were familiar to me as a former radar technician and instructor in the US Navy. These pulses would also be useful for carrying out saturation in order to measure spin–lattice relaxation times. Little did I know at the time that Henry Torrey⁷ had already succeeded in measuring nutations at Rutgers by applying rf pulses which remained on for long time periods in order to record as many nutation oscillations as possible. Unfortunately for Torrey, his pulse lengths and time sequences were too long to allow the discovery of free precession and echo signals. Luckily for me, it will be seen next that I was destined to discover free induction and spin echoes by accident because I turned on rf pulse power over shorter time periods, using pulse sequences in pairs in order to measure relaxation times.

After I wrote my thesis which dealt with measurements of nutations, spin–lattice relaxation times,⁸ and adiabatic fast passage effects, I remained another year (1949–50) at Illinois as a postdoc. Through the summer of 1949 I continued further investigations of nutations and was about to write up my results in detail. However, I gave up when Torrey came out with his nutation paper⁷ which scooped me completely. I only went as far as publishing an abstract⁹ and continued instead to do more nutation measurements with increased rf pulse power, thinking that the larger amplitude and higher frequency nutation signals might be a useful way of achieving better NMR sensitivity. That was a naive idea of no value, but the experimental setup provided conditions for the accident by which I discovered spin echoes.

My use of pulses permitted measurements of short spin–lattice relaxation times in the millisecond domain. The scheme was as follows: when an rf pulse was turned on, it lasted long enough for a 60 cycle one-half sine wave of magnetic sweep field to pass through nuclear resonance at the middle of the pulse. The pulse voltage was balanced to a sufficient null by a bridge circuit so that the receiver was not saturated and could detect the absorption ‘v mode’ signals

which appeared on top of a pedestal, a small leakage of the pulse itself due to a slight bridge unbalance. Starting at thermal equilibrium with a first pulse, the signal at the top of the pedestal due to that pulse was compared, after a known time delay with no rf excitation, to a smaller 'v mode' signal on top of a second delayed pedestal caused by an applied second pulse. The second signal amplitude relative to the first one indicated spin-lattice relaxation recovery of magnetization following the saturation caused by the first pulse. By varying known times between first and second pulses, spin-lattice relaxation times were determined in proton samples such as glycerine and water.⁸ All signals were synchronized with 60 cycles. In a sweep time of one period of 60 cycles, the oscilloscope face displayed a single 'v mode' signal on top of each pedestal, and zero signal during sweeps with time delay and no rf pulse excitation.

Finally one day the weird signal appeared. For no good reason, except maybe to measure as many points as possible, I increased the pulse power and narrowed the pulse width considerably, to a time of the order of a millisecond or less. The result—a 'v mode' type of signal which looked strangely symmetric—appeared on the oscilloscope in the absence of a pulse and its corresponding pedestal. But I did not admit to that observation at the time as a genuine signal, and cursed at it as an annoying glitch. I twiddled the pulse width knob back to a wider pulse and the glitch went away. Off-handedly, on the day of that observation (late summer 1949), I blamed the glitch on an erratic misfiring of a multivibrator gate.

A week went by and luckily I fooled with the pulse width knob again. Up popped the signal with no pulse to account for it. The signal, of course, was the spin echo, and this time I nursed and cajoled the then mysterious blip with various maneuvers. I realized that the 60 cycle modulation was an annoyance and removed it. The symmetric signal had a definite amplitude dependence on pulse intensity and pulse width. After displaying the two pulse sequence in one slow single sweep (from protons in glycerine), all the standard characteristics of echo behavior fell out in front of my astonished eyes like a cornucopia from Mother Nature.

I stuck a screwdriver in the magnet and the echo width narrowed because of the increase in field inhomogeneity. Later I looked at the echo decay envelope of protons in water, and it was startlingly different. Compared to glycerine the water decay envelope no longer looked exponential, but was rather Gaussian in character. This was the signature of self-diffusion, a deduction which took me a while to realize only after I noticed that the Gaussian decay depended on the strength of the field gradient. In short order, all of the characteristics of damping and various echoes with their delays showed up with more than two pulses.¹⁰ Although the pulses were narrow enough to permit the formation of an echo, they were at first too wide to allow perceptible FID signals until the pulses were made even narrower. The FID told me immediately that I had free precession, but to figure out the various echoes from three pulses, including the very interesting stimulated echo, I had to sit down with Bloch's equations and figure out first why two equal pulses produced an echo. This effort would have been simplified considerably if I had first conceived of the 90–180 ° pulse echo pancake model demonstrated later¹¹ by Carr and Purcell. I devised my own more complicated two-dimensional vector models for primary and stimulated echoes which follow after the application of two and then three

identical pulses. After I announced the discovery of the echo, I was honored by a letter of congratulations from Ed Purcell in which he sketched his three-dimensional 'eight-ball' picture of the 90–90 ° spin echo. To say the least, so many new effects came out in such a short time that I was bewildered and shaky with excitement. It was only a few days after I confirmed the signal as genuine that I happened to look at the echoes from the protons in alcohol and saw the mysterious beat modulation of the echo envelope. That was too much! I had a lot of explaining to do!

I had the good fortune to overlap with Charlie Slichter for about a year after he arrived from Harvard. He just finished his Ph.D. as a student of Ed Purcell. I profited from his presence as the first member of the Illinois Physics Faculty in NMR who helped me enormously. An important example: Charlie advised me about the correct statistical mathematical approach to analyze the effects of spin diffusion on the damping of echo signals. Charlie was the first outside denizen of NMR with whom I was in constant contact and who I feel was the first of the Physics Faculty to sense the significance of my discoveries. Dick Norberg, who was Slichter's first graduate research student, shared lab space with me in the so-called 'Physics Penthouse Loft' on the top floor of the old physics building. Dick was a beneficial stimulus in bringing up all sorts of interesting questions, and encouraging me not to delay further the writing of a major paper¹² because I was trying solve all the mysteries at once before doing so.

I should mention here that Arnold Nordsieck became my nominal thesis advisor after James Bartlett went on sabbatical leave, just as I was beginning my thesis project. Nordsieck did not follow what I was doing nor was he interested when I told him later about the echoes. He was so preoccupied with the design and construction of an analog computer that he absolutely avoided all distractions. Nevertheless I owe my thanks to Nordsieck. As a theoretician who at one time had worked with Felix Bloch, Nordsieck convinced Bloch to take me on as a postdoc fellow at Stanford when it became time for me to leave Illinois. I was very fortunate to win a one year National Research Council Fellowship (not easy to get in those days). So off to Stanford I went in the fall of 1950.

STANFORD, 1950–52

Indirect Spin-Spin Interaction

When I first arrived at Stanford, I remember vividly my first contact with Felix Bloch. He was sitting on a lab stool in the basement of the old 'Physics Corner' hunched over a chart recorder, inspecting NMR signals newly obtained by his students huddled around him. The Stanford group specialized in hunting and confirming new spins and magnetic moments. In the course of making spectroscopic searches, the effects of chemical shifts and indirect spin-spin interactions fell out of their data. At first they considered these as a nuisance, complicating their spectroscopy. Earlier the group at Stanford reported the observation¹³ of a field-independent splitting of ¹²¹Sb in the SbF₆⁻ ion. The physical origin of the splitting, quite different from the chemical shift, was not confirmed. Martin Packard and colleagues had first displayed the celebrated proton chemical shift spectrum of alcohol, later

accompanied by the field-independent fine structure splitting with improved resolution.¹⁴ This spectrum turned out to be the steady-state counterpart of the mysterious echo envelope beats I first saw¹² in alcohol.

In retrospect, my first days with Felix Bloch were a precious and privileged experience. Soon after my arrival Bloch took off several afternoons and grilled me about my spin echo results. I outlined the mystery of the echo envelope beats, and Bloch agreed that I should build an echo rig and track down the cause of the beats. I discussed with him at length a model involving first-order interactions between two groups of spins, coupled to one another, distinguished by different chemical shifts. However the model, often applied to simple chemical reactions, is only dissipative and would not predict beats. This idea did come in handy later however, when it was realized how chemical exchange would modify or average out '*J* coupling', by virtue of proton spin exchange which I observed in methyl and ethyl alcohol.

I really did not know how to manipulate the quantum mechanics of spins in a genuine facile manner when I began my research at Stanford. I learned from Bloch how to calculate echo pulse sequences quantum mechanically, beginning with a pertinent Hamiltonian, rather than just to rely on his macroscopic equations. There was no way to predict the envelope beats from modified Bloch equations. Gutowsky et al. reported splittings¹⁵ in liquids, which appeared to be the remnant (as a brief speculation discounted by them¹⁶) of the magnetic dipole-dipole interaction because of hindered rotation. After noting certain empirical results from their data, they confirmed¹⁶ that the $J \mathbf{I}_1 \cdot \mathbf{I}_2$ exchange term would account for their observations, and described them in detail later in a major paper.¹⁷ Independently, I found it necessary to choose the same term in order to explain echo modulation beats. Since the Illinois measurements were made in the steady state and mine were in the transient regime, I had the wrong impression at first that my experiment elicited an effect that could only occur in the time domain. In the steady state, if the NMR splittings of spins were caused by local fields of nonresonant coupled foreign spin species, they did not show up in terms of echo envelope beats. Apparently my magnetic field inhomogeneity was too large at first to resolve the beat oscillations (within a single echo or FID) due to coupled foreign spins.

I first thought of the exchange interaction in terms of the overlap of nuclear wavefunctions, a mechanism infinitesimally small which we never took seriously and out of the question unless one believes in cold fusion. I simply cut my teeth by carrying out a quantum mechanical echo calculation which incorporated into the Hamiltonian chemical shift terms which distinguish one proton species from its coupled neighbor; knowing about the form of the exchange operator from Heisenberg's model for ferromagnetism, I added the $J \mathbf{I}_1 \cdot \mathbf{I}_2$ exchange term. This calculation showed that at least two chemically inequivalent spin species (such as the CH₃ and CH₂ groups in alcohol) had to be excited simultaneously by the two-pulse sequence in order to display echo envelope beats. The mystery in my mind was then solved as to why echo envelope *J* coupling beats would not result if the spins were all equivalent.

Don Maxwell was assigned to me as my first graduate thesis student. In our major paper¹⁸ we presented the experiment and theory for various cases of proton spin couplings in molecules.

The paper discusses some ideas using rate equations about the influence of chemical exchange on the attenuation of envelope beats, and presents the results of damping in the time domain rather than translating them into the frequency domain. Slichter and McConnell¹⁹ presented related and clearly more useful interpretations of reactions and line narrowing in the frequency domain.

After we published our initial proton echo envelope results in a letter side-by-side with a letter by MacNeil et al.²⁰ of the Illinois group (they reported results concerning their measurements of fluorine echo envelope 'slow beats'), Ramsey and Purcell identified²¹ the physical origin of the '*J*' coefficient as the effect of indirect exchange, caused by nuclear hyperfine interactions. At the news of this explanation, Bloch called me into his office and literally apologized to me. He said he should have thought of this idea himself because he was well aware of the nuclear hyperfine interaction. In fact later as a joke, after Don Maxwell and I wrote our paper and acknowledged the advice and encouragement of Bloch at the end of the paper, Bloch read it and chortled 'You should have acknowledged me for my constant discouragement!'

It was clear to me why Bloch didn't think of the origin of the interaction. In his view all of these effects were 'chemical' and not sufficiently fundamental. Many times Bloch indicated he would not be caught up in the morass of solving problems related to chemical structure and worry about the mystery of the field-independent splitting. On one occasion when Dick Norberg visited Stanford, and he and I were telling Felix at length about our results, finally Bloch said 'Hahn, you should be a chemist, and Norberg, you should be a metallurgist!' (Norberg was studying the NMR of hydrogen adsorbed in platinum and palladium.) Later, when NMR proved to be extremely important for chemical analysis and MRI, Bloch changed his views and indeed he was very interested.

As a junior citizen, my sojourn at Stanford came to an end. It was the policy of the Stanford Physics Department at that time to hire 'at the top' and not to promise a ladder appointment to young upstarts like me. Sid Drell, who graduated with me at Illinois, was also at Stanford at the same time and had the same fate. I should mention that Drell gave me very helpful advice about theory; and of course Felix Bloch inculcated in me many concepts without which I would not have succeeded in rounding out my understanding of my research results at Stanford. In 1952 I took a research position at IBM Watson Laboratory in New York City, and Drell went to MIT. Eventually I went to Berkeley and Drell returned to Stanford.

IBM WATSON LABORATORY, 1952-55

I was hired as a research physicist by the IBM Watson Computing Lab at Columbia and entered a new research group. In hiring me, IBM expressed an interest in the possibility that spin echoes might be useful for digital memory in computers. I took a dim view of their interest for fear that I would be channeled into doing applied research. I took the job on the basis that there was to be no obligation on my part to lead a research program in spin echo memory, that I would serve only as a consultant. Even at that time one could sense that spin echo memory would be too slow and of low capacity, which proved to be the case.

Spin Echo Memory

On the subject of how the practicality of the spin echo method was viewed in those early days, it should be pointed out that while I was at Stanford, Russell Varian advised me to write up a patent²² on the applications of pulsed nuclear induction. Chemical analysis appeared to be its main use. With the support of the Varian patent staff I wrote up the patent. In order to do this however I had to ask the ONR, and subsequently the University of Illinois, to release the patent rights to me, which they did. As a good example of how small-scale research results can be immediately viewed with utter boredom and no foresight by higher authority, the President of the University of Illinois sent me a formal letter of release of their patent rights, which stated '... the spin echo is a phenomenon of Nature ...', with words to the effect that it would be of no use. (On the contrary, the spin echo is absolutely an 'unnatural phenomenon'! Ludwig Boltzmann would have said the same thing!) Stuck somewhere in that patent written for Varian was the suggestion, as well as in one of my papers, that there might be a possible application to computer memory. When the University of Illinois heard that IBM was interested in spin echo memory they regretted their decision to release the spin echo patent and tried to renege.

Spin echo memory for computing proved to be of no use. The outcome of IBM spin echo memory research consisted of a few IBM patents written by my research colleagues who contributed a number of original ideas. A very interesting summarizing paper²³ was published which confirmed the behavior of inverse order multiple transverse echo pulse memory and direct order multiple longitudinal stimulated echo pulse memory. These memories could be separated from one another by the application of magnetic field gradient pulses, thus eliminating the interference of any nonlinear higher order echoes. This paper introduced several ideas about manipulations and pulse sequences which later found their way into magnetic resonance imaging (MRI) and photon stimulated echo pulse memory experiments in rare earth crystals.²⁴

Zero-Field NQR Echoes

At IBM Watson Laboratory, I was given the status of an associate in the Columbia University Physics Department and taught a course in atomic physics. I took on Bernard Herzog as a beginning graduate thesis student and we worked on the problem of detecting zero-field ³⁵Cl nuclear quadrupole spin echoes using the 'workhorse' crystal of sodium chlorate. Zero-field CW NQR had been discovered²⁵ by Dehmelt and Kruger, and it was natural to look for spin echoes in this novel nuclear quadrupole coupled regime. Meyer Bloom, Slichter's student at Illinois, was doing the same experiment for his thesis, unknown to us at first. There was some question at the time about how one should expect to see a signal from crossed coils, beginning from thermal equilibrium, when the zero net spin angular momentum of the spin ensemble results from the spin degeneracy of the quadrupole moments in zero field. Admittedly after some fumbling and bumbling we finally got a signal, which could only be picked up from the same coil that was excited with an rf pulse. We realized only later that the application of a small magnetic field would permit a modulation signal to be seen even in a cross coil at right

angles to the excited coil. Meyer Bloom apparently saw his signal shortly before we did at Watson laboratory, but he kindly agreed that we publish a paper²⁶ together. In that paper Bloom contributed an interesting echo envelope modulation effect which occurs when the two-pulse echo is generated within the FID lifetime following the second pulse. Also in that paper, although not recognized as such because it was not in the language of the density matrix, we presented a formulation of the pseudo two-level spin system from which we devised a vector model.

The 'workhorse' crystal, sodium chlorate, which made its debut with zero-field NQR echoes, served later as a model two-level system that displayed the effects of SEDOR,²⁷ cross spin polarization transfer,²⁸ spin noise,²⁹ and finally nuclear quadrupole induced atomic electric dipole oscillations³⁰ (the inverse of the Stark effect in NQR).

SEDOR—Spin Echo Double Resonance

The $J \mathbf{I}_1 \cdot \mathbf{I}_2$ interaction in liquids indicated to me that the turnover of a spin would alter the precession phase of the spin echo of its neighbor because of the magnetic dipole-dipole interaction in a solid. This property led to the following experiment: a separate rf resonance pulse was applied to flip the sodium spin neighbors of ³⁵Cl in sodium chlorate during the application of the second pulse of a two-pulse sequence to obtain the ³⁵Cl spin echo at its own precession frequency. The resonance of sodium is therefore detected indirectly when the scrambling of phases due to local dipolar fields of sodium at the ³⁵Cl sites causes a maximum reduction in the ³⁵Cl echo amplitude. Hence the SEDOR (Spin Echo Double Resonance) method was adopted as the thesis of Bernard Herzog. Measurements of the attenuation of the echo envelope were carried out as a function of the extent of phase scrambling caused by the SEDOR process. A model²⁷ based upon stochastic predictions of the Fokker-Planck equation was applied to fit the data.

UNIVERSITY OF CALIFORNIA, BERKELEY, 1955–91

Cross-Relaxation Polarization Transfer

After settling down in Berkeley I pursued further SEDOR spectroscopy and relaxation experiments, which finally constituted the graduate theses of Kaplan and Emschwiller.³¹ At the same time I mused a great deal over ways one could increase the double resonance sensitivity, if only the time for scrambling phases could be significantly increased. However phase scrambling was not a good approach because the echo memory relaxation time of ' T_2 ' for echoes in solids is at best no longer than a few milliseconds. Could a longer time of the order of the spin-lattice relaxation time ' T_1 ' be exploited instead? Here is where Sven Hartmann came into the picture—a very perceptive thesis student who was a match for an entirely new kind of experiment.

The so-called Hartmann-Hahn cross-relaxation experiment²⁸ evolved from hints contained in Al Redfield's famous paper.³² These hints were to be found in his discussion of 'rotary saturation' and in his concept of spin temperature in
